We are forever indebted to the individuals whose efforts have transformed the field of retinal dystrophies into the dynamic and growing field it is today. We dedicate this work to the spirit of collaboration critical to achieving major breakthroughs in genetic diagnosis and treatments.

Sarwar Zahid

Preface

Although the practice of medicine has changed over the centuries, the core principle of “First, do no harm” laid down by Hippocrates remains a central tenet. As the field of genetic testing has rapidly advanced into next-generation sequencing and to whole exome and whole genome sequencing, there has been a rapid proliferation of information available to patients and physicians. However, as a profession, we must exercise caution when giving patients genetic diagnoses. We hope that this book will help health-care professionals make genotype-phenotype correlations. When we encounter genetic variants that were previously unreported or that are of unknown significance, we encourage physicians and genetic counselors to refer to the relevant chapters in this book to gain an understanding of variable expression of these inherited retinal diseases.

Writing and collecting images for this book has been a team effort. Physicians, genetic counselors, and researchers from three institutions (Oregon Health & Science University, Casey Eye Institute; Moorfields Eye Hospital; and University of Michigan, Kellogg Eye Center) came together through friendship to complete the colossal task of compiling these book chapters, with the shared goal of helping physicians and patients better understand these conditions.

In Shakespeare’s *King Lear*, Gloucester, who has been blinded and thrown out of the kingdom, hides, stripped of all his dignities, and Edgar, his banished son, comes to save him from his misery. This is not just an act of saving a blind individual but an act of love and obligation. We are all Edgars in medicine—we love our patients and our profession, and we are obligated to our patients from the day we decide to practice medicine.

It is only by working together that we can advance this field of “orphan” diseases. As therapeutic clinical trials are initiated, let us collaborate to share our precious patients as subjects in the trials that show the most promise. Let us stand united in protecting our patients, while also informing them of opportunities to partake in therapeutic trials. We must carefully weigh the risks and benefits for each patient rather than our obligations to companies running particular clinical trials.

Let us keep in perspective the reason for participating in these trials in the first place—the improvement of vision or halting of progressive loss of vision in patients affected by inherited retinal diseases. We want to be able to encourage children and adults newly diagnosed with retinal dystrophies that treatments for these conditions are in the not-too-distant future.

ABCA4 encodes an ATP-binding cassette transporter expressed in cone and rod photoreceptors that is responsible for the transport of N-retinyl-phosphatidyl-ethanolamine and all-trans-retinaldehyde as part of the visual cycle. Recessively inherited mutations can cause a variety of *ABCA4*-related retinopathies that includes Stargardt disease, fundus flavimaculatus, retinitis pigmentosa (rod-cone dystrophy)-like phenotype, cone dystrophy, and cone-rod dystrophy [1–3].

Patients with Stargardt disease (STGD) typically present with central visual dysfunction (reduced visual acuity, dyschromatopsia, and reduced contrast sensitivity) in the first-to-second decades. A second common presentation is in early adulthood with less rapidly progressive disease than in those with the childhood-onset form. A minority of patients present in later life, in their 40s through 60s, with relatively stable visual acuity, and relatively preserved foveal structure and function – ‘foveal sparing STGD’ [4]. The extent of visual acuity deterioration is often variable and reflects involvement of the fovea, ranging from better than 20/40 to worse than 20/200. Patients who present later are more likely to maintain acuity better than 20/200 than those who present with childhood onset disease [5]. The degree of photosensitivity or night blindness/peripheral visual field loss is variable, ranging from unaffected to severely affected, and can be determined with electrophysiological assessment (see below).

Typical fundus findings include central macular atrophy and yellow-white flecks at the posterior pole, primarily at the level of the RPE (Figs. 1.1a, 1.2b, 1.3a, 1.4a, and 1.5a). There is, however, considerable phenotypic heterogeneity, including the presence/absence, distribution, and extent of flecks and retinal pigmentary changes (Fig. 1.2a), and the degree of macular atrophy, which can also have a bull’s-eye maculopathy (BEM)-like pattern (Fig. 1.3a, b). Approximately a third of patients with non-toxic BEM harbor disease-causing variants in *ABCA4* [6]. Before the identification of the gene *ABCA4*, fundus flavimaculatus (FFM) was used to describe patients with retinal flecks but no ophthalmoscopic evidence of macular atrophy; following the discovery that *ABCA4* mutations cause both STGD and FFM, the term FFM is now rarely used.

Three electrophysiological phenotypes with prognostic implications have been identified in STGD [7, 8]. Patients in group 1 have dysfunction confined to the macula; group 2 have macular and generalized cone system dysfunction; and group 3 have macular, generalized cone, and generalized rod system dysfunction. A longitudinal study of patients with STGD found that all patients with initial rod dysfunction on electroretinography (ERG) demonstrated clinically significant electrophysiologic deterioration; only 20% of patients with normal full-field ERGs at baseline showed clinically significant progression [8]. Patients with group 3 STGD have central scotomata on Goldmann visual field (GVF), in keeping with all patients with STGD, with progressively constricting peripheral fields, and thereby experience more severe visual impairment [9].

Fundus autofluorescence (FAF) can identify a characteristic pattern of areas of increased and decreased autofluorescence (AF) at the posterior pole, with centrally reduced AF corresponding with macular atrophy, which can aid diagnosis, especially in childhood. In advanced disease, peripapillary sparing of AF can be helpful in suggesting *ABCA4*-related disease [10, 11]. In addition, FAF has a role in monitoring progression by determining changes in AF over time (Figs. 1.1b and 1.5b) [8, 12]. A longitudinal study of FAF in STGD found that the AF pattern at baseline influences the enlargement of macular atrophy over time and has genetic correlates [8]. Fluorescein angiography (FA) may reveal a “dark choroid” (Fig. 1.4b), but this is less commonly seen since the advent of FAF and increasing accessibility of genetic testing have made FA less crucial to diagnosis [13]. If extensive atrophy precludes visualization of a dark choroid, the diagnosis may be suggested by the presence of a peripapillary hypofluorescent ring on FA (peripapillary dark choroid ring), also seen as a preserved area on FAF imaging [14]. However, absence of a dark choroid does not exclude *ABCA4*-associated disease; some patients with less extensive disease may not exhibit a dark choroid [2]. Additionally, auto-contrast features on modern fundus cameras may render a dark choroid difficult to visualize.

Fig. 1.1 Case summary: 21-year-old female with Stargardt disease. (a) Color fundus photograph of the right eye showing minimal macular flecks with an area of central macular atrophy. (b) Fundus autofluorescence of the right eye showing increased macular autofluorescence with

hyperautofluorescent small flecks. There is also central hypoautofluorescence in the area of macular atrophy, which is better visualized with autofluorescence imaging.

Fig. 1.2 Case summary: 8-year-old with mutations in *ABCA4*. (a) Color fundus photograph at age 8 years showing a normal-appearing fundus except for an occasional fleck-like lesion in the right eye, despite 20/200 visual acuity. There was an identical visual

acuity and fundus appearance in the left eye. (b) Color fundus photograph at age 11 years, showing the development of foveal atrophy and increased flecks in the posterior pole.

Bull's-eye maculopathy (BEM) is characterized by a distinct lesion at the macula (Fig. 1.3a, b) [6]. Three distinct FAF phenotypes have been described by Kurz-Levin et al. depending on relative hyper- or hypoautofluorescence inside and outside the bull's-eye lesion [15]. BEM associated with

ABCA4 mutations may be observed in the context of cone-rod dystrophy or STGD. *ABCA4* has been implicated in at least 30% of recessive cone-rod dystrophy [16]. These patients usually present in their first-to-second decades with blurred vision and reduced visual acuity; night blindness and

Fig. 1.3 Case summary: 29-year-old male with bull's-eye maculopathy. (a) Color fundus photograph of the right eye showing a bull's-eye atrophy lesion in the macula surrounded by retinal deposits. (b)

Fluorescein angiography of the right eye (AV-transit phase) showing a window defect in the area of bull's eye atrophy. The deposits exhibit hyperfluorescent staining.

Fig. 1.4 Case summary: 24-year-old female with mutations in *ABCA4*. (a) Wide-field color fundus photograph of the right eye showing diffuse pisciform flecks throughout the posterior pole without any associated

atrophy. (b) Wide-field fluorescein angiography (AV-transit phase) showing hyperfluorescent staining of the flecks on the background of a dark choroid.

peripheral visual field loss typically occur later [17]. Visual acuity may range from 20/30 in children to worse than 20/200 to LP late in the disease process, but there is marked variability [17]. Some groups have also described individual patients with certain solitary heterozygous mutations and milder, later-onset disease, but it is unclear if the single *ABCA4* mutation in these patients is causative [18, 19].

Mutations in *ABCA4* have rarely been reported to cause an autosomal recessive retinitis pigmentosa (RP)-like phenotype. These patients usually present with night blindness in the first-to-second decade with very poor visual acuity. Fundus findings include the classical findings of RP, such as optic disc pallor, attenuated vessels, and bone-spicule pigment deposits, as well as posterior pole atrophy [20].

Fig. 1.5 Case summary: 13-year-old girl with Stargardt disease. (a) Color fundus photograph of the right eye showing flecks throughout the macula without any obvious macular atrophy. (b) Fundus autofluorescence of the right eye showing hyperautofluorescence of the flecks on a

background of increased macular autofluorescence. There is a central focus of hypoautofluorescence suggestive of atrophy that is not obvious on fundus photography.

Fig. 1.6 Wide-field fundus photographs of the right and left eyes from a 64-year-old male with a rod-cone dystrophy-like phenotype with diffuse bone spicule pigment deposition and atrophy with a non-recordable

ERG and with peripheral islands of remaining visual fields on Goldmann Visual Field testing.

ERG and GVF usually reveal a rod-cone pattern of degeneration (Fig. 1.6).

The carrier frequency of likely pathogenic *ABCA4* alleles has been reported to be as high as 1:20, and over 700 *ABCA4* variants have so far been identified. The high allelic heterogeneity makes molecular genetic analyses of *ABCA4*-associated retinal disease very challenging. It has been reported that direct Sanger sequencing of the entire *ABCA4* coding region (50 exons) detects between 66% and 80% of

disease-causing alleles; however, this approach has significant limitations in large patient cohorts due to the prohibitive time and cost implications [21].

Since the development of the *ABCA4* genotyping microarray using arrayed primer extension (APEX) technology, systematic screening of all known previously reported *ABCA4* variants has been available; APEX detects approximately 65–75% of all disease-associated alleles. However, by definition, novel variants are not detected by APEX technology,

necessitating the use of other methodologies for high-throughput systematic screening of the entire coding region, especially in cases where one or both disease-causing alleles have not been identified by the array.

Zernant et al. reported the capability of a next-generation sequencing (NGS) strategy to detect new *ABCA4* variants that were not included on the APEX array; all 50 *ABCA4* exons of 168 patients were amplified in parallel using an amplicon tagging polymerase chain reaction (PCR) protocol, and NGS was applied to the resulting amplicons [22]. This NGS strategy has been repeated in another cohort with similar findings, identifying the second disease-causing allele in 48% of the cohort in whom only one allele had been previously found with APEX [8]. These findings suggest that many disease-associated mutations in the *ABCA4* gene are very rare and yet unknown, supporting the validity of the PCR-enrichment-based NGS method either as the screening method of choice or as an additional screening method for patients in whom APEX does not reveal two variants.

AIPL1 encodes aryl-hydrocarbon interacting protein-like 1, which is a protein that may be important for protein folding and trafficking, expressed in the developing and adult photoreceptor layer. It has also been shown to affect photoreceptor function as well as signal transduction through its mediation of cone PDE6 and RetGC1, respectively [1]. Mutations in *AIPL1* cause recessive Leber congenital amaurosis (LCA) and juvenile-onset rod-cone dystrophy, dominant cone-rod dystrophy has also been reported.

AIPL1 mutations cause 4–8% of LCA [2]. Patients typically present within the first year of life. Patients may experience night blindness, photosensitivity, or photoattraction. Franceschetti's oculo-digital sign, pendular nystagmus, keratoconus (more common in patients with homozygous mutations), and cataracts are commonly observed. Visual acuities range from 20/400 to light perception (median of LP) [3]. The fundus may be normal at an early age, but later in disease it usually shows optic nerve pallor, bone-spicule pigmentary deposits in up to 84% of patients (ranging from mild mid-periphery deposits to severe, diffuse deposits and chorioretinal atrophy), and maculopathy in up to 80% of patients (ranging from mild foveal atrophy to macular stippling, aplasia, or atrophy within first decade) that worsens over time (Figs. 2.1, and 2.2) [4, 5]. Retinal white dots have also been reported in some patients by Tan et al. [6]. Maculopathy, keratoconus, and cataracts are more likely in patients with LCA caused by *AIPL1* mutations than in those with *RPE65* and *GUCY2D* mutations [4]. Electroretinogram (ERG) has been shown to be non-recordable in most patients at an early age, and Golmann visual field (GVF) reveals undetectable or very limited visual fields [7].

However, in three young patients with *AIPL1* mutations, Pennesi et al. reported some residual scotopic ERG function and more preserved visual fields [8]. Tan et al. have also reported residual rod function in a 2-year-old patient [6]. Optical coherence tomography (OCT) may reveal loss of foveal photoreceptors, loss of the outer nuclear layer, reduced foveal thickness, increased inner retinal thickness, or lamellar disorganization.

Juvenile-onset rod-cone dystrophy caused by recessively-inherited mutations in *AIPL1* has been reported in patients who presented with reduced acuity, decreased peripheral vision, and night blindness in the first decade of life. These patients gradually lose acuity and peripheral vision with time. Visual acuity may be as good as 20/60 in their 40s, but it declines steadily to worse than 20/400 within two decades [7]. Keratoconus has not been reported. Fundus findings may include preservation of RPE in the macula, with a bull's-eye lesion and pigmentary atrophy in the mid-periphery beyond the attenuated arcades (Fig. 2.3a–c). Optic nerve drusen have also been reported. Near-infrared imaging may reveal areas of depigmentation, and fundus autofluorescence may show areas of atrophy and hyperautofluorescent bone-spicule pigment deposits (using NIR-RAFI). OCT shows foveal atrophy, loss of photoreceptors and the ONL, and increased thickness in certain retinal areas [7]. GVF reveals a rod-cone pattern with peripheral constriction and loss, with a central functional island that is lost with age. ERG reveals residual but significantly reduced rod and cone parameters (90% reduction in one study) [7].

There has been a report by Sohocki et al. [2] of dominantly-inherited cone-rod dystrophy caused by a mutation in *AIPL1*.

Fig. 2.1 Case summary: 24-year-old female with juvenile-onset rod-cone dystrophy. (a) Color fundus photographs of the right eye showing a bull's-eye lesion at the macula with atrophy at age 18. (b) Montage of color fundus photographs of the right eye showing a bull's-eye lesion at the macula with peripheral bone spicule pigmentation with atrophy at age 25. ALMS1 encodes a protein involved in ciliary function and/or ciliogenesis and is located at the ciliary basal body [1, 2]. Mutations are responsible for a progressive cone-rod dystrophy associated with systemic features—Alström syndrome (AS).

ALMS1 mutations are the only reported mutations responsible for AS [3], in the class of ciliopathies [4], and are inherited in an autosomal recessive pattern [5]. The prevalence of AS is about one per million [3]. Onset of the condition is in infancy, with photosensitivity and nystagmus as the commonly observed first symptoms [6–9]. Progressive cone-rod dystrophy is the hallmark of the disease [7]. The disease shows significant phenotypic interfamilial and intrafamilial variability with respect to age of onset and rate of progression [8]. In general, however, progression seems more rapid than is typical of other cone-rod dystrophies [8, 9]. In a cohort of three Swedish patients, all children showed 20/100–2/200 visual acuity at age 3 [8]. In another study of seven affected children from five unrelated non-consanguineous Chinese families, all patients observed (ages 5–14) exhibited best corrected visual acuity of 20/200 to light perception [3]. Bilateral subcapsular cataracts may also be observed in patients with AS [8, 10]. Fundus exam shows attenuation of retinal vessels [3, 10], optic disc pallor, retinal pigment epithelium (RPE) atrophy [8, 10], and may show the presence of drusen (Fig. 3.1a) [9]. Some individuals show narrowing of vessels and depigmentation early in life, but others may not show any abnormal features on fundus exam before the age of 8–10 years [8]. Asteroid hyalosis, optic disc drusen, and bone spicules may also be present [10]; one patient was reported to show a bull’s-eye lesion in the macula [8]. Optical coherence tomography

(OCT) shows thinning of the RPE and ellipsoid zone [3, 9] and early arrest of macular development in 5-year-old children [9, 10], with persistent inner retinal layers and absent connecting cilia in the outer retina (Fig. 3.1b) [9]. Electroretinography correlates with the degree of visual acuity loss, showing early cone involvement and subsequent rod degeneration. Cone response varies from undetectable at 4–6 months [8, 10] to slightly reduced at 10 years. Rod response is usually within normal limits in infancy and may show marked reduction or be nonresponsive by 5–6 years [8, 10], or may have only minor loss by age 10 [8]. Goldmann Visual Field (GVF) results vary widely between patients, with some showing fields as constricted as <5° on V:4e isopter by age 12 and others showing 50° of field on the I:4e isopter at age 10 [8]. Color vision also varies greatly, with some patients showing normal color vision at age 10 and others showing a complete loss of color vision at age 12 [8].

Other symptoms include bilateral sensorineural hearing loss, which often presents in childhood, but can present at any time from infancy to adulthood [10], type 2 diabetes mellitus, truncal obesity, dilated cardiomyopathy, craniofacial features, hypothyroidism, elevation of liver transaminases, renal insufficiency, gonadal dysfunction, menstrual irregularities [5, 11], and adolescent cessation of growth, leading to short stature and scoliosis [7]. Unlike Bardet-Biedl Syndrome, another ciliopathy, polydactyly is not generally seen (although there have been reports of polydactyly and syndactyly in up to 2% of patients with AS [8]), while sensorineural hearing loss is [4]. Morbidity and mortality are usually due to multiple organ failure from hepatic, cardiac, pulmonary, and renal fibrosis [7].

Fig. 3.1 Case summary: 11-year-old female (CEI24864) with homozygous *ALMS1* mutation c.6436C>T p.Arg2146X. Poor vision (LP OU). History of diabetes mellitus type 2, vitreous hemorrhage in both eyes, status-post pars plana vitrectomy in the left eye. (a) Color fundus

photograph of the left eye showing peripheral retinal RPE changes. (b) Spectral domain-optical coherence tomography showing outer retinal atrophy with loss of the ellipsoid zone throughout the macula.

ARL6, or *BBS3*, encodes a protein that binds the ciliary membrane protein complex containing seven BBS (Bardet-Biedl syndrome) proteins [1]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [2] and for syndromic features associated with Bardet-Biedl syndrome (BBS). *ARL6* mutations may also cause isolated retinitis pigmentosa (RP) [3, 4].

ARL6 mutations are responsible for a large percentage of cases of autosomal recessive Bardet-Biedl syndrome in Saudi patients, reported by Abu Safieh et al. [4] to have been seen in three out of seven families with BBS. Mutations in *ARL6* are rarely seen in other populations, however, with only two families affected with this mutation in a cohort of 163 families affected with BBS of North American, European, Newfoundlandian, Turkish, Iraqi, Pakistani, and Indian descent [5]. In a Danish study, mean age at diagnosis for BBS was 11.8 years [6]. In a study conducted in Brazil, only 21% of patients with BBS had a visual acuity above 20/40 in their better-seeing eye [2]. Night blindness may be observed in patients with *ARL6* mutations as early as age 5 [7]. Bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [2]. Central vision has been shown to decline 1 line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [2]; 73% of BBS patients are legally blind by their teens or twenties [8]. Some reports suggest that individuals with BBS caused by mutations in *BBS1* exhibit the mildest phenotype and best visual acuity [6, 9]. In contrast, Abu Safieh et al. [4] claim that mutations in *ARL6* tend to cause the mildest phenotypes. Patients with mutations in *ARL6* are also reportedly more likely to be myopic [8]. However, some researchers claim that there is no significant genotype-phenotype correlation for BBS [2]. On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal pigment epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral

pigmentation [2]. While the fundus findings include surface wrinkling or mild bone spicule-like pigmentation in some patients, most patients were sine pigmenta (without pigment) [8]. Younger patients tend to show milder changes, such as peripapillary atrophy and mild patchy changes of the internal limiting membrane. Older patients with mutations in *ARL6* typically show more advanced retinal atrophy and macular atrophic changes. Some patients may exhibit posterior subcapsular cataracts [8]. Optical coherence tomography in patients with BBS shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination [10]. On electroretinography, scotopic rod and maximal responses were non-detectable in 91.3%, while cone responses were non-detectable in 65.2%. All patients who could be assessed had elevated dark-adapted visual thresholds [2].

Syndromic features of those with Bardet-Biedl syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [11, 12]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [11, 13]. It has been reported that individuals with mutations in *ARL6* more often have polydactyly of all four limbs [13].

There has been a reported case of an individual with a mutation in *ARL6* who had an isolated finding of retinitis pigmentosa [3, 4] without other systemic features.

BBS1 encodes Bardet-Biedl syndrome 1 protein, which is part of the BBSome complex (*BBS1–9*) and is thought to be involved in ciliogenesis. Mutations in *BBS1* are associated with Bardet-Biedl syndrome (BBS) and non-syndromic retinitis pigmentosa [1, 2]. BBS is characterized by retinal degeneration and several systemic manifestations, including truncal obesity, muscular-skeletal abnormalities (such as polydactyly, syndactyly, brachydactyly, and/or clinodactyly), genitourinary tract abnormalities (renal cysts), impaired secondary sexual development (e.g., hypogonadism, virilism), deafness, and varying degrees of cognitive and behavioral abnormalities [3]. *BBS1*-related BBS follows an autosomal recessive pattern of inheritance. *BBS1* is the most commonly affected gene in BBS, accounting for approximately 23% of cases. Polydactyly is typically diagnosed in infancy and often the only residual evidence of this may be scars at the sites of removed digits. Patients with retinal manifestations may present with (syndromic) or without (non-syndromic) other extraocular manifestations of the spectrum of BBS [2].

Patients typically present with night blindness within their first two decades of life. Visual acuities may be good (20/40 to 20/50) initially, but progressively decrease over time. Visual acuities may be better in *BBS1*-related disease than in BBS caused by other genes, such as *BBS2*, *BBS3*, *BBS5*, *BBS7*, *BBS10*, and *BBS12* [4]. Cataracts are commonly observed in both the syndromic and non-syndromic

RP populations with *BBS1* mutations. Fundus examination typically reveals bone spicules and arteriole attenuation [5]. There also may be atrophic maculopathy as the disease progresses, as well as bull's eye maculopathy (Figs. 5.1a, 5.2a, 5.3a, and 5.4a). Retinal pigment epithelium (RPE) atrophy may also be observed in the arcades. Goldmann visual fields typically reveal ring scotomas with field loss predominantly in the periphery. Electroretinogram (ERG) typically shows a rod-cone pattern of degeneration and often becomes nonrecordable at an early age [2, 6]. ERG parameters have been shown to be higher in retinopathy caused by *BBS1* than in RP caused by mutations in other genes [4]. Negative ERGs have also been reported in some patients [6, 7]. Optical coherence tomography (OCT) may reveal foveal, retinal, and outer nuclear layer thinning in the macula, including loss and disruption of the ellipsoid zone, but retinal lamination is usually maintained. Cystoid macular edema is common (Figs. 5.3c and 5.4c) [6–8]. Fundus autofluorescence may exhibit rings of foveal hyperfluorescence as well as hypofluorescent macular atrophy, sometimes in a bull's eye pattern (Figs. 5.1b, 5.2b, 5.3b, and 5.4b) [7]. There is significant phenotypic variability, even in patients harboring the same mutation, with manifestations ranging from a limited maculopathy to diffuse retinal dysfunction [6]. Some of the phenotypic variability is thought to be related to oligogenic epistatic interactions with mutations at other loci [9], but variability has also been demonstrated in the absence of such modifiers [6].

BBS2 encodes one of seven Bardet-Biedl Syndrome (BBS) proteins that form the stable core of a protein complex required for ciliogenesis and that have a likely function in membrane trafficking to the primary cilium [1]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [2] and for syndromic features associated with Bardet-Biedl Syndrome.

BBS2 mutations are responsible for about 8–18% of autosomal recessive Bardet-Biedl syndrome [3–6]. Mutations in this gene are most common in the Bedouin population in the Negev Desert in Israel [4, 7]. They have also been seen at the increased frequency of 28.6% in a cohort of 14 Iranian families [8]. A recurring mutation in this gene is Y24X, which is most common in individuals with European ancestry [5]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [3, 6, 9–11], but, statistically, this could just be due to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [6]. In a Danish study, mean age at diagnosis for individuals with mutations in *BBS2* was 7.8 years [6]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better-seeing eye [2]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [2]. Central vision has been shown to decline one line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [2]; 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [10]. It has been claimed that individuals with mutations in *BBS2* and *BBS10* have more severe phenotypes than those with mutations in *BBS1* [6], but obesity tends not to be as commonly observed

in patients with mutations in *BBS2* [12]. Some investigators claim, however, that there is no significant genotype-phenotype correlation for BBS [2, 13]. In general, visual function has been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend [10]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [10].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal pigment epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation (Fig. 6.1a, b) [2]. In an Israeli family with individuals affected with mutations in *BBS2*, surface retinal wrinkling was seen mostly in childhood, primarily at the posterior pole, and was mostly observed around the vessels in older patients. There was no significant bone spicule-like pigmentation in the family [7]. OCT in individuals with BBS shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination (Fig. 6.1c) [10]. On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. In the Israeli family with *BBS2* mutations, the youngest child (age 4) had a mixed cone-rod response that was 11% of normal, while the 17-year-old demonstrated a nonrecordable ERG response. All patients with BBS who could be assessed had elevated dark-adapted visual thresholds [2].

Syndromic features of those with Bardet-Biedl Syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [14, 15]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension (Fig. 6.1) [12, 14].

Fig. 6.1 Case Summary: 27-year-old female with Bardet-Biedl syndrome (BBS) with homozygous mutations in *BBS2* (c.1237C > T) with best-corrected visual acuity 3/36 in both eyes. (a, b) Color fundus photos of the right (montage) and left eyes showing patchy RPE atrophy throughout the macula, macular atrophy, and sparse peripheral pigment deposits. The macular atrophy in the left fundus is associated with dense pigmentary changes. (c, d) Fundus autofluorescence of the right

and left eyes showing small areas of hypoautofluorescence (corresponding to RPE atrophy) early in the disease state, followed by (e, f) larger areas of hypoautofluorescence in a background of relative hyperautofluorescence, showing disease progression over the course of years. (g, h) Spectral domain optical coherence tomography of the right and left eyes showing extensive macular ellipsoid zone loss, deposits above the RPE, and trace epiretinal membranes in both eyes.

BBS4 encodes one of seven Bardet-Biedl Syndrome (BBS) proteins that form the stable core of a protein complex required for ciliogenesis and that have a likely function in membrane trafficking to the primary cilium [1, 2]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [3] and for syndromic features associated with Bardet-Biedl Syndrome.

BBS4 mutations were responsible for about 14% of autosomal recessive Bardet-Biedl syndrome cases in a study of 14 Iranian families [4] and for about 1.2% of cases seen at the Berman-Gund laboratory in Massachusetts [5]. *BBS4* mutations are more frequently found in populations in the Middle East [6]. It is the most commonly mutated gene in cases of Bardet-Biedl in Turkish and Pakistani populations [4, 7] and is also one of the more commonly mutated genes in cases of BBS in the Bedouin population in the Negev Desert in Israel [5].

Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [8–12], but, statistically, this could just be due to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [11].

In a study of three pairs of siblings with BBS due to mutations in *BBS4*, the mean age of onset of retinal dystrophy was 4 years, with a range of 2–7 years [13]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better-seeing eye [3]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [3]. Central vision for those with BBS is expected to decline one line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [3]; 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [10].

It has been claimed that individuals with mutations in *BBS4* are more likely to have high myopia than other

patients with BBS [5, 14], that they tend to have more significant and earlier-onset obesity [6, 15], and that they more frequently have polydactyly only of the upper limbs [6, 16]. Some researchers claim, however, that there is no significant genotype-phenotype correlation for BBS [3, 17]. In general, visual function has been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend [10]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [10].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation [3]. In a study with three pairs of siblings with *BBS4* mutations, all six patients had “amorphous” pigment deposits rather than bone spicules [13]. Fundus autofluorescence may show hyperautofluorescence at the fovea and peripheral patchy hypoautofluorescence in areas of retinal pigment epithelium atrophy and pigment deposition (Fig. 7.1a). Optical coherence tomography in individuals with BBS shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination (Fig. 7.1b) [10]. On electroretinography, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2% [3]. In a study of three pairs of siblings with *BBS4* mutations, all had non-recordable rod and cone responses on ERG, and the youngest was 13 years old at the age of evaluation [17]. In a study of 23 patients with BBS, all patients who could be assessed had elevated dark-adapted visual thresholds [3].

Syndromic features of those with Bardet-Biedl Syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [18, 19]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [16, 18] (Fig. 7.1).

Fig. 7.1 Case Summary: 13-year-old female (CEI25963) with rod-cone dystrophy as a manifestation of Bardet-Biedl Syndrome with a homozygous splicing donor site mutation (IVS10 + 1G > A, CEI 2011) in *BBS4*. (a) Fundus autofluorescence of the left eye showing hyperau-

tofluorescence at the fovea and peripheral patchy retinal pigment epithelium atrophy. (b) Spectral domain optical coherence tomography showing a faint epiretinal membrane and extensive loss of the ellipsoid zone.

BBS5 encodes one of seven Bardet-Biedl Syndrome (BBS) proteins that form the stable core of a protein complex required for ciliogenesis and that have a likely function in membrane trafficking to the primary cilium [1]. *BBS5* in particular has a possible role in regulating light-dependent translocation of arrestin1, which moves between photoreceptor inner and outer segments according to light conditions [2]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [3] and for syndromic features associated with BBS.

BBS5 mutations are responsible for about 2–3% of autosomal recessive BBS [4–6], mostly from non-European ethnic backgrounds [7]. Mutations in *BBS5*, along with mutations in *BBS4* and *BBS8*, are particularly common in patients with BBS from the Middle East and Africa [8]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [9–13], but, statistically, this could be simply due to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [12].

In a Danish study, mean age at diagnosis for BBS was 11.8 years [12]. In a study conducted in Brazil, only 21% of patients with BBS had a visual acuity above 20/40 in their better-seeing eye [3]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [3]. Central vision for those with

BBS is expected to decline 1 line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [3]; 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [11]. Visual function has been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend [11]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone versus cone-rod dystrophy [11].

On fundus examination, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation [3]. Optical coherence tomography shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination [11]. On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. All patients who could be assessed had elevated dark-adapted visual thresholds [3].

Syndromic features of those with BBS include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [14, 15]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [14, 16].

Fig. 8.1 Case summary: 42 year old man with Bardet-Biedl Syndrome. (a) Widefield color fundus photo of the right eye, showing diffuse retinal atrophy and pigment clumping. (b) Widefield fundus autofluorescence of the right eye, demonstrating patches of hypoautofluorescence

in the posterior pole, with widespread mottled hypoautofluorescence throughout the retina. (c) Spectral Domain Optical Coherence Tomography of the right eye, showing diffuse retinal thinning, loss of the ellipsoid zone, and foveal atrophy.

BBS7 encodes one of seven Bardet-Biedl Syndrome (BBS) proteins that form the stable core of a protein complex required for ciliogenesis and that have a likely function in membrane trafficking to the primary cilium [1]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [2] and for syndromic features associated with BBS. Ocular features vary widely, however. In a Chinese family with *BBS7* mutations, patients were found to have macular dystrophy rather than typical retinitis pigmentosa (RP) findings [3].

BBS7 mutations are usually described as being responsible for about 2–9% of autosomal recessive Bardet-Biedl syndrome [4–8]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [9–13], but, statistically, this could be due simply to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [12].

In a Danish study, mean age at diagnosis for BBS was 11.8 years [12]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better eye [2]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [2]. Central vision for those with BBS is expected to decline 1 line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [2]; 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [11]. In general, visual function has

been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [11].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation [2]. In a Chinese family with BBS due to *BBS7* mutations, patients had attenuated vessels, chorioretinal atrophy and scarring, as well as optic disc pallor [3]. OCT in individuals with BBS shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination [11]. It was observed that five patients from Toronto with *BBS7* mutations had reduced retinal thickness, with less preservation of retinal layers across similar age groups than patients with mutations in *BBS1* and *BBS10*, who had previously been reported [4]. On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. All patients with BBS who could be assessed had elevated dark-adapted visual thresholds [2].

Syndromic features of those with Bardet-Biedl Syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [14, 15]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [14, 16].

BBS9 encodes one of seven Bardet-Biedl Syndrome (BBS) proteins that form the stable core of a protein complex required for ciliogenesis and that have a likely function in membrane trafficking to the primary cilium [1]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [2] and for syndromic features associated with BBS.

BBS9 mutations are generally reported to be responsible for about 1–4% of autosomal recessive BBS [3, 4]. In a cohort of 14 patients with BBS in Iran, however, 14% of the patients had mutations in *BBS9* [4]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [5–9], but, statistically, this could be due simply to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [8].

In a Danish study, mean age at diagnosis for BBS was 11.8 years [8]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better eye [2]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [2]. Central vision for those with BBS is expected to decline 1 line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in

dark-adapted environments [2]; about 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [7]. In general, visual function has been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend [7]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [7].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation [2]. OCT in individuals with BBS shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination [7]. On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. All patients with BBS who could be assessed had elevated dark-adapted visual thresholds [2].

Syndromic features of those with BBS include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [10, 11]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [10, 12].

BBS10 encodes a protein that is part of the type II chaperonin family and that, along with *BBS12*, localizes to the basal body of primary cilia and is responsible for ciliogenesis and adipogenesis [1, 2]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [3] and for syndromic features associated with Bardet-Biedl syndrome (BBS).

BBS10 mutations are responsible for around 20% [1, 4, 5] to 43% [6] of autosomal recessive Bardet-Biedl syndrome, which appears to have a similar frequency in families of European and Middle Eastern ancestry [4]. However, this frequency was found to be as low as 7.6% in a Spanish cohort [7]. The most common mutation in *BBS10* is a 1-bp insertion (271dupT), causing premature termination 4 codons later (C91LfsX5). This mutation accounts for about 26% [1] to 46% [4] of *BBS10* mutant alleles and is most frequent in those of European descent [4, 8], but it is also seen in Turkish and Afghan families [4]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [1, 6, 9, 10], but, statistically, this could just be due to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [6]. There has also been a reported case of an individual with four mutations in *BBS10* who was shown to have a more severe phenotype overall [1]. In a Danish study, mean age at diagnosis for individuals with mutations in *BBS10* was 8.7 years [6]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better eye [3]. Night blindness is typically observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [3]. Central vision for those with BBS is expected to decline one line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [3]; about 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [1]. It has been

claimed that the phenotype of individuals with mutations in *BBS10* is more severe and has a lower visual acuity and smaller visual field areas [11] than those with mutations in *BBS1* [1, 5, 8, 11]. Some researchers claim, however, that there is no significant genotype-phenotype correlation for BBS [3]. In general, visual function has been seen to deteriorate with age, but the range of refractive errors has no significant trend [1]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [1]. For patients with mutations in *BBS10*, nystagmus was observed in 16 of 23 patients, and cataract (including “mild” cataract) was noted in 9 of 20 [1].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal pigment epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation (Fig. 11.1a–d) [3]. On OCT, those with mutations in *BBS10* and *BBS1* show preserved inner retinal layers and outer nuclear layer, disrupted IS/OS layer, thinned RPE, and reduced (but present) photoreceptor inner or outer segment layer in the foveal area (Fig. 11.1e–f) [11]. Deposits adjacent and anterior to Bruch’s membrane, which could be related to retinal reorganization, are more evident in those with *BBS10* than with *BBS1* mutations [11]. Internal limiting membrane wrinkling was seen in 3 of 8 patients with *BBS10* or *BBS1* mutations [11]. On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. All patients who could be assessed had elevated dark-adapted visual thresholds [3].

Syndromic features of those with Bardet-Biedl syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [12, 13]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [12, 14].

Fig. 11.1 Case Summary: 26-year-old female with Bardet-Biedl syndrome with heterozygous mutations in *BBS10* (c.899A > C; c.306delCAGA) with best-corrected visual acuity of 1/60 in both eyes. (a, b) Color fundus photos of the right and left eyes showing extensive macular atrophy with pigmentary changes and diffuse RPE dropout along the arcades and midperipheral retina with pig-

mentary changes. (c, d) Fundus autofluorescence of the right and left eyes showing macular and diffuse patchy areas of hypoautofluorescence corresponding to areas of atrophy. (e, f) Spectral domain optical coherence tomography of the right and left eyes showing extensive macular ellipsoid zone loss and subretinal deposits above the RPE.

BBS12 encodes a protein that is part of the chaperonin family and that, along with *BBS10*, localizes to the basal body of primary cilia and is responsible for ciliogenesis and adipogenesis [1, 2]. Mutations are responsible for rod-cone (86.9%) and cone-rod (13.1%) dystrophies [3] and for syndromic features associated with Bardet-Biedl syndrome (BBS).

BBS12 mutations are responsible for about 3–11% [1, 4–7] of autosomal recessive Bardet-Biedl syndrome. A study conducted in France and the US showed most of these families to be Caucasian [7], while a study conducted in Canada showed most of them to be of non-European ancestry [1]. A study of 14 Iranian families with BBS reported the prevalence of mutations in *BBS12* to be as high as 21.4% [8]. Additionally, some researchers have reported digenic triallelic inheritance of BBS, also known as the triallelic hypothesis [1, 6, 9, 10], although statistically, this could just be due to the presence of rare polymorphisms or the recognized carrier frequency of mutations in these other BBS genes [6]. It also appears that *BBS12* is rarely a partner in digenic inheritance [11]. In a Danish study, mean age at diagnosis for BBS was 11.8 years [6]. In a study conducted in Brazil, only 21% of patients with Bardet-Biedl had a visual acuity above 20/40 in their better eye [3]. Night blindness (nyctalopia) is generally observed in those with BBS by age 9, and bilateral nystagmus has been observed in 26% of BBS patients, some of whom also demonstrated strabismus [3]. Central vision for those with BBS is expected to decline one line per year on the logMAR chart, while peripheral vision declines at 0.19 log units per year in dark-adapted environments [3]; about 88% of BBS patients (from a cohort with mutations in *BBS6*, *BBS10*, or *BBS12*) are legally blind by age 18 [1]. It has been claimed that the phenotype of individuals with mutations in *BBS12* and *BBS10* have a more rapid progression of visual loss than those with mutations in *BBS6* [1], but it has also been claimed those with mutations in *BBS12* and *BBS1* have a milder phenotype than those with *BBS10* mutations [12]. Some researchers claim, however, that there are

no significant genotype-phenotype correlations for BBS [3, 7]. In general, visual function has been seen to deteriorate with age in BBS, but the range of refractive errors has no significant trend [1]. There appears to be no statistically significant genotype-phenotype correlation for rod-cone vs. cone-rod dystrophy [1].

On fundus exam, 42.8% of BBS patients show disc pallor, 67% show attenuated retinal vessels, 67% show widespread retinal pigment epithelium abnormalities, 42.8% show macular abnormalities, and 23.8% show peripheral pigmentation [3] (Fig. 12.1a–d). OCT shows thinning of the photoreceptor layer, with preservation of the inner retinal lamination [1] (Fig. 12.1e–f). On ERG, scotopic rod and maximal responses were non-detectable in 91.3% of those with BBS, and cone responses were non-detectable in 65.2%. All patients who could be assessed had elevated dark-adapted visual thresholds [3].

Syndromic features of those with Bardet-Biedl syndrome include hyperphagia-induced obesity, intellectual disability, renal anomalies, polydactyly, and hypogenitalism [13, 14]. Other features include developmental delay, speech delay, congenital heart disease, poor coordination, hypodontia, and increased incidence of diabetes mellitus and hypertension [13, 15].

There has been a report of three individuals who carried the homozygous mutation p.S701X in the *BBS12* gene, which is closer to the C-terminal end of the encoded protein than any other reported pathogenic mutations in *BBS12* [15]. These patients were siblings from a consanguineous Pakistani family who exhibited a milder phenotype for BBS, showing only postaxial polydactyly, hypodontia, and late-onset retinal dysfunction; with no renal or genital anomalies, obesity, learning disability, or other symptoms of BBS. Night blindness for these patients began at age 13–15, while daytime vision was only mildly impaired by the ages of 30, 27, and 19. All three exhibited rod-cone dystrophy, myopia, and astigmatism, and none of them met clinical diagnostic criteria for BBS [15].

Fig. 12.1 Case summary: 51-year-old male with Bardet-Biedl syndrome with homozygous mutations in *BBS12* (c.1418_1420del) with best-corrected visual acuity of 2/60 in the right eye and 3/20 in the left eye. **(a, b)** Color fundus photographs of the right and left eyes showing large circular areas of chorioretinal atrophy limited to the central maculae in both eyes. Retinal pigment epithelium atrophy is also apparent in areas along the arcades in both eyes. **(c, d)** Fundus autofluorescence of the right and left eyes showing circular areas of hypoautofluorescence in the macula and outside the arcades in both eyes, corresponding to

areas of RPE/photoreceptor atrophy. There are also areas of hyperautofluorescence along the arcades in both eyes in areas without atrophy. In the right eye, there is progression of atrophy demonstrated along the superior arcades, with the areas of hypoautofluorescence extending to areas that were previously hyperautofluorescent. **(e, f)** Spectral domain optical coherence tomography of the right and left eyes showing profound RPE and ellipsoid zone atrophy with areas of scarring in both eyes, and showing inner retinal cystic cavities and an epiretinal membrane in the right eye.

BEST1 encodes bestrophin-1, a Ca^{2+} -dependent protein in the RPE. Mutations in *BEST1* cause dominant Best vitelliform macular dystrophy (BVMD), adult-onset foveomacular vitelliform dystrophy (AOFVD), autosomal dominant vitreoretinopathopathy (ADVRC), microcornea, rod-cone dystrophy, cataract, posterior staphyloma (MRCS) syndrome, and autosomal recessive bestrophinopathy (ARB) [1].

BVMD is an autosomal-dominant macular dystrophy that presents with reduced visual acuity, metamorphopsia, photophobia, or night blindness, with an age of onset ranging from early childhood to the sixties (mean 33 years) [1]. Hyperopia is very common. Visual acuity gradually declines with age, especially during the vitelliform disease stages, but may remain stable in some patients for many years. Choroidal neovascularization (CNV), which may result in a more rapid reduction of visual acuity, has been reported to occur in up to 9% of patients with BVMD and usually occurs in the context of scarring (Fig. 13.1a–b). CNV typically responds to conventional anti-VEGF treatments.

The fundus exhibits classical stages as depicted, beginning with normal to slightly altered macular RPE changes (pre-vitelliform stage), and then progressing to a characteristic “egg-yolk” macular lesion (Fig. 13.2a), which then becomes “scrambled” in the subsequent stage (Figs. 13.3 and 13.4a). Thereafter, there is a “pseudohypopyon” stage that exhibits a fluid level containing yellow material inferiorly, which is followed by atrophy and scarring of the choroid and retina. There was previously thought to be a linear progression between these stages, but there is evidence that patients can progress and regress between stages, and they often exhibit two different stages in each eye; there may even be variable stages represented within a single lesion. There have been reports of patients in the final scarred stage who maintain good visual acuity [2].

In early stages of disease, fluorescein angiography reveals hypofluorescence due to the vitelliform lesion obstructing the choroidal signal, while later stages of disease are characterized by hyperfluorescence in areas of atrophy, which man-

ifest as window defects. Fundus autofluorescence (FAF) reveals a high intensity signal in the areas where yellowish fundoscopic lesions are located (Figs. 13.2b and 13.4b); the inferior yellow material-filled region of the pseudohypopyon lesion is usually hyperautofluorescent on FAF. As with AMD, this progresses to well-defined hypofluorescence in the atrophic stages.

The earliest OCT finding is thickening of the photoreceptor outer segments, which can be observed to elongate during light adaption. Later OCT findings, including scars and CNV, are characterized by hyperreflective sub-retinal material and occasional sub-RPE deposits (Fig. 13.2c) [3]. As the disease progresses, the subretinal material often partially liquefies and becomes hyporefective on OCT. In the final stages, OCT demonstrates central retinal atrophy.

The electro-oculogram (EOG), a measure of the ocular standing potential, is abnormal, with an Arden ratio less than 1.5. This can be abnormal even before patients exhibit any fundoscopic signs of disease. The reduction in the light peak of the EOG is due to the mutant Bestrophin (expressed in both and macular and peripheral RPE) having an abnormal large scale voltage-gated chloride channel conductance in the RPE [4]. However, there have also been reports of several patients with BVMD with normal EOGs. Full-field ERG and dark adaptation are usually normal, while multifocal ERG is usually abnormal. One study, which used multifocal ERG in the context of subretinal fluid, has shown that the extent of structural abnormalities correlates with the extent of functional abnormalities [5].

Of note, some mutations have been reported to exhibit a more rapid decline in visual acuity than others [1]. Genotype-phenotype correlations have been challenging, given extensive intra- and interfamilial phenotypic variability [1, 6–10]. There has also been a report of a patient with a homozygous dominant mutation and a more severe phenotype, with early reduction of rod ERG parameters and a multifocal vitelliform retinopathy [11].

Null *BEST1* mutations carried in the homozygous or compound heterozygous states cause autosomal recessive

Fig. 13.1 Case summary: 8-year-old with Best disease. (a) Color fundus photograph of the left eye showing two pigmented lesions, one near the fovea and another superotemporal to the optic nerve. The central lesion represents choroidal neovascularization, is surrounded by RPE

depigmentation, and appears to be elevated. (b) Late-phase fluorescein angiography of the left eye showing leakage at the neovascular membrane in the central macula, and window defects with staining surrounding the lesion.

bestrophinopathy (ARB), in which patients present at an average age of 23 years (range 4–40 years) with central vision deficits, hyperopia, and shallow anterior chambers [12]. These patients are at elevated risk of developing angle-closure glaucoma due to their shallow anterior chamber anatomy. Fundus findings include central RPE changes with vitelliform deposits, edema, and subretinal fluid. EOG, pattern ERG, multifocal ERG, and full-field ERG are all usually abnormal. FFA reveals patchy areas of hyper- and hypofluorescence corresponding to areas of atrophy and edema, while FAF shows areas of increased signal, with lipofuscin accumulation and decreased signal in areas of atrophy. Carriers of mutations associated with autosomal recessive bestrophinopathy are completely normal. There have been reports of some patients with biallelic mutations in *BEST1* who exhibit a BVMD phenotype rather than recessive bestrophinopathy [13].

BEST1 mutations may also cause a proportion of AOFVD, a subtype of pattern dystrophy, with an average age of onset of reduced visual acuity and metamorphopsia in the fifties. Visual acuity may remain stable or progressively deteriorate with time, depending on foveal atrophy or CNV (up to 15%). The characteristic fundoscopic lesion is round and yellow/white with a pigmented spot in the fovea bilaterally; the size of the lesion is variable, but it is usually smaller than the optic disc. The lesion may appear similar to the lesions seen in the spectrum of BVMD (vitelliform “egg-yolk” lesion >1DD), and there may be multiple lesions in the same eye. EOG and full-field ERG are typically normal or mildly

reduced, whereas multifocal ERG reveals central dysfunction. Color vision may be abnormal, and central scotoma may be present in up to half of patients [16]. Fluorescein angiography usually reveals blockage of fluorescence at the lesion, but, some may exhibit areas of patchy increased signal. FAF patterns seen in AOFVD are variable. One study has shown that reduced foveal OCT cross-sectional thickness correlates with worse visual acuity [14]. Some studies have suggested that AOFVD caused by *BEST1* mutations may actually just be a milder form of BVMD, given the later average age of onset and better visual acuity early in the disease course [15, 16].

BEST1 mutations also cause ADVIRC. This disease can present with rotary nystagmus, cataracts (usually at a young age and often posterior subcapsular), hyperopia, shallow anterior chamber, and nanophthalmos, and many patients develop angle-closure glaucoma. Fundus findings are characterized by circumferential dark pigmentary deposits that start in the peripheral retina and progress inwards, chorioretinal atrophy surrounding the disc and in the mid-periphery, white punctate deposits, and fibrillar degenerative vitreous strands; retinal vascular attenuation and disc pallor may also be observed [17, 18].

Visual acuity is generally stable throughout life, given the macular sparing, but it may deteriorate in patients who develop macular edema, central macular atrophy, retinal detachment, or vitreous hemorrhage. EOG and full-field ERG are usually abnormal, displaying loss of rod and cone function, although both of these modalities have been

Fig. 13.2 Case summary: 7-year-old girl with Best disease. (a) Color fundus photograph of the right eye showing a classic egg yolk vitelliform lesion in the macula. (b) Fundus autofluorescence of the right eye showing hyperautofluorescence within the classic egg yolk vitelliform

lesion. (c) Spectral domain optical coherence tomography of the right eye showing the extent of the vitelliform lesion in the subretinal space with disruption of the ellipsoid zone and shadowing posteriorly to the lesion.

reported to be within normal limits in some patients. As in rod-cone dystrophy, the GVF reveals a gradually constricting peripheral field.

MRCS syndrome is caused by mutations in *BEST1* and is characterized by microcornea, rod-cone dystrophy, cataract, and staphyloma [19]. Some patients experience night blindness as the initial symptom, and visual acuity usually declines after the third decade due to a combination of cataracts and photoreceptor dysfunction. Posterior staphyloma with normal ocular axial lengths and pulverulent cataracts at a young age are both very common. Fundus features include peripheral atrophy and pigment deposits that progress centrally with age. Full-field ERG reveals a rod-cone pattern of degeneration, and the EOG is invariably abnor-

mal. Some studies have suggested that MRCS syndrome is on a spectrum of disease with ADVIRC, given reports of some patients in a family carrying an MRCS-associated mutation exhibiting nanophthalmos without posterior staphyloma. Mutations affecting splicing are associated with ADVIRC and MRCS.

Of note, there has also been a case series showing an association between *BEST1* mutations and retinoschisis in two siblings [20]. In these cases, patients presented with blurry vision and reduced visual acuity during childhood. Fundoscopy and OCT revealed retinoschisis, serous retinal detachments, and increased retinal thickness, while FFA demonstrated hyperfluorescent spots in the retina, and full-field ERG parameters were within normal limits.

CACNA1F encodes a voltage-dependent calcium channel involved in signal transmission from rod and cone photoreceptors to the inner retina [1]. Mutations are X-linked and have been reported to cause 55% of congenital stationary night blindness (CSNB). They have also been associated with cone-rod dystrophy, Aland Eye Disease, and retinal and optic disc atrophy [2–7].

Patients with CSNB present in the first decade with nystagmus (52%) or at a later age with reduced visual acuity (range 20/30–20/200), night blindness (observed in only 39% of patients), low-to-moderate myopia, abnormal color vision (normal, tritan, or non-specific), and strabismus (24%) [8]. The fundus is usually normal, but myopic degeneration can be seen in patients with high myopia (Figs. 14.1 and 14.2a). ERG reveals a characteristic negative ERG, in which the b-wave to a-wave ratio is less than 1 for the bright flash scotopic b-wave (Fig. 14.2b). Unlike patients with mutations in *NYX*, patients with *CACNA1F* mutations often demonstrate some preservation of the dim scotopic b-wave (giving rise to the term “incomplete CSNB”), and not all patients with *CACNA1F* mutations exhibit a negative ERG (75% in some studies) [8]. The flicker amplitude is often reduced, although not extinguished, and it can exhibit a double-peaked wave [2].

Cone-rod dystrophy caused by mutations in *CACNA1F* may present in childhood or adulthood [9, 10]. Patients pres-

ent with reduced visual acuity (20/40–20/300), central scotomata, and color vision defects (protan defects or normal color vision is also possible). Myopia is commonly observed; nystagmus is uncommon. ERG reveals reduced flicker amplitudes and may exhibit a negative ERG. The fundus is often normal, but there may be myopic degeneration in patients with high myopia.

Mutations in *CACNA1F* can also cause Aland Eye Disease, which is characterized by a hypopigmented fundus, reduced visual acuity secondary to foveal hypoplasia, nystagmus, and color vision deficits (often protan) [5]. It has been described as a stationary disease except for the progressive myopia. ERG reveals defects in both rods and cones.

Nakamura et al. have also reported a unique phenotype caused by mutations in *CACNA1F* [6]. These patients experience progressively deteriorating visual acuity and visual fields that correspond to funduscopy evidence of retinal and optic disc atrophy with attenuated retinal vessels. GVF may show central scotomata and visual field constriction. ERG has been reported to reveal a negative waveform, but it generally shows more severe and diffuse retinal dysfunction than is typically patients with CSNB as described above. The same mutations that cause this unique phenotype may also cause CSNB, illustrating the phenotypic variability associated with *CACNA1F* mutations.

CEP290 encodes a centrosomal protein involved in ciliary assembly and ciliary trafficking. Mutations are responsible for autosomal recessive Leber's congenital amaurosis (LCA), Joubert syndrome, and Bardet-Biedl Syndrome [1–3].

Recessive *CEP290* mutations are responsible for 15–20% of LCA. Patients typically have profound vision loss that manifests at birth or within the first few months of life, with one study showing that 64% of patients exhibit CF acuity in the better eye at presentation [4]. However, there have been reports of intrafamilial variability in visual acuity in affected families, and some patients may have acuities better than 20/200 [1]. In some patients, visual acuity may even be as good as 20/25 [4]. This same study suggests that vision may remain relatively stable over time in this disease. Symptomatology includes pendular nystagmus, high hypermetropia, photodysphoria, oculodigital sign, keratoconus, and cataracts [5]. Some patients may have associated systemic findings, such as abnormal proprioception, infertility, and mental retardation. Funduscopy appearance is variable and may include peripapillary atrophy, arteriolar narrowing, foveal dysgenesis, RPE atrophy with nummular or bone spicule pigmentation, and optic disc pallor (Figs. 15.1a and 15.2a). Fundus autofluorescence may show a hyperautofluorescent ring around the fovea (Figs. 15.1b and 15.2b). Coloboma and Coats-like vasculopathy are also observed.

Electroretinography (ERG) exhibits globally reduced rod and cone function.

Joubert syndrome is a genetic disease resulting from cerebellar vermis hypo/a-plasia that manifests with hypotonia; ataxia; mental retardation; hyperpnea; oculomotor apraxia; polydactyly; cleft lip/palate; tongue, kidney, and liver defects; and seizures. Patients with recessive *CEP290* mutations may also exhibit retinopathy as part of Joubert syndrome and associated disorders, manifesting vision loss within the first few months to years of life [2]. Clinical findings may include chorioretinal colobomas and classical findings of retinitis pigmentosa (RP) (e.g., bone-spicule pigment deposits, retinal vascular attenuation, etc).

Recessively-inherited mutations in *CEP290* are also associated with Bardet-Biedl Syndrome, a pleiotropic genetic disorder that includes a diverse array of manifestations, most commonly including obesity, polydactyly, hypogonadism, renal dysfunction, and retinitis pigmentosa [5–7]. The ophthalmic manifestations occur early in life and usually begin with night blindness in the first decade, progressing to peripheral visual loss and a maculopathy later in life, accompanied by the classical RP findings of bone-spicule pigmentary deposits and progressive retinal atrophy and concomitant loss of visual fields. However, patients may also present with central visual deficits and progress to subsequent peripheral vision loss. By the second to third decade, almost 75% of patients are legally blind.

CERKL encodes ceramide kinase-like protein, and mutations in this gene are associated with autosomal recessive cone-rod dystrophy [1–7]. Biallelic *CERKL* mutations cause up to 5% of recessive retinitis pigmentosa in Spain and are also common in the Yemenite Jewish population [2, 3, 5].

Patients with *CERKL*-related cone-rod dystrophy typically present in their teens or twenties (median of 23 years) with night blindness and central visual deficits, but symptoms may occur as early as the first decade [3, 5, 8]. Photophobia is very common. Some patients may exhibit early-onset posterior subcapsular cataracts [2, 5]. Visual acuity is usually maintained into early adulthood but then rapidly declines with macular atrophy (range from 20/50 to LP in older patients) [2]. Fundus findings feature macular abnormalities, ranging from mild pigmentary changes to macular atrophy, attenuated retinal vessels, and variable degrees of peripheral changes (ranging from mid-peripheral bone spicule deposits to a “salt and pepper” appearance) [3, 8]. Macular and peripheral atrophy worsen with time and are clinically manifested as a progressive loss of visual fields and acuity. Some patients may exhibit pigment accumulation in areas of well-defined macular atrophy (Figs. 16.1a and 16.2a); atrophic areas may become confluent and resemble gyrate atrophy [2, 5]. Macular changes

may be evident as early as 15 years of age, and in some patients with maculopathy, the periphery is initially normal [3]. Many patients exhibit normal coloration of the optic disc [1, 2]. Full-field ERGs demonstrate severe abnormalities of both rod- and cone-driven function, and these recordings may demonstrate a cone-rod pattern in some patients [3, 4]. ERGs are non-recordable in many older patients [2]. GVF often reveals constriction of peripheral fields with a central scotoma in the context of macular atrophy or annular loss of fields surrounding a residual central island. Late in the disease process, some patients exhibit absolute scotoma [2–4]. FAF reveals hypoautofluorescence in areas of macular atrophy and a broad ring of hyperfluorescence around the perifovea (Figs. 16.1b and 16.2b). OCT may show thinning of the fovea with loss of the outer nuclear layer (ONL) or abnormal lamination. Some patients may exhibit areas of OCT hyperreflectivity in the ONL and inner segment-outer segment line (Fig. 16.1c); these areas exhibit heterogenous FAF signals, characterized by both hyper- and hypoautofluorescence [4]. The ONL and ellipsoid zone are reduced in and around the fovea, especially in the areas of highest cone and rod densities [4]. Given the early macular involvement, many patients receive a diagnosis of cone-rod dystrophy.

Fig. 16.1 Case summary: 20 year-old-man with a cone-rod dystrophy with mutations in *CERKL*. (a) Montage color fundus photograph of the right eye showing macular atrophy with subretinal deposits. (b) Fundus autofluorescence of the right eye showing macular hypoautofluores-

cence in areas of atrophy with a hyperautofluorescent ring near the vascular arcades. (c) Spectral domain optical coherence tomography of the right eye showing extrafoveal ellipsoid zone and outer nuclear layer loss with subretinal deposits in areas of residual photoreceptors.

CHM encodes Rab Escort Protein, or REP1, which binds unprenylated Rab proteins involved in vesicle transport. Mutations in *CHM* are associated with choroideremia [1, 2].

Choroideremia is an X-linked progressive chorioretinal dystrophy. Affected male patients typically experience night blindness in the first or second decade of life, followed by progressive visual field constriction [1]. Visual acuities are usually 20/40 or better in the first-to-fourth decades but subsequently deteriorate to 20/200 or less and in some cases to no light perception in the elderly [1, 3–5]. Visual fields show mid-peripheral isolated scotomata with progressive constriction over time [3, 5, 6]. Fundus examination typically shows lobular choroidal and retinal/RPE atrophy, which starts in the periphery and later coalesces into widespread chorioretinal atrophy down to bare sclera, with progressive constriction over time and macular sparing until the fifth to sixth decades (Figs. 17.1a, 17.2, and 17.4) [1, 3, 5]. Unlike retinitis pigmentosa, retinal vascular caliber and optic nerve appearance remain relatively normal. Fundus autofluorescence (FAF) demonstrates isolated

peripheral areas of reduced autofluorescence (AF) early in the disease, which progress to large lobular areas of reduced AF in advanced disease (Fig. 17.3a) [8]. Optical coherence tomography (OCT) shows outer retinal atrophy with foveal sparing until later stages and outer choroidal thinning with increased reflectance due to RPE loss (Figs. 17.1b and 17.3b) [5, 9]. Cystoid macular edema may be seen. Full-field electroretinograms (ERG) show significantly reduced rod and cone responses, which may be non-recordable in later stages of disease [5, 6]. Rarely, there may be a negative electroretinogram [8].

Female carriers are typically asymptomatic, but, due to skewed X-inactivation, may show areas of peripheral retinal and RPE pigmentary disturbance with variable increasing chorioretinal involvement with age (Fig. 17.4). OCT of female carriers may vary, but when abnormal it may demonstrate remodeling over time, including focal thickening of the outer retina and drusen-like deposits corresponding with areas of increased AF [9]. ERGs may be normal or show mild reduction of amplitudes [1, 6, 7].

CLN3 encodes battenin, a protein involved in lysosomal function and neuronal transport. Mutations in this gene are associated with a syndromic retinal degeneration, Batten disease, or juvenile neuronal ceroid lipofuscinosis (JNCL), as well as non-syndromic retinal degeneration [1].

CLN3-related JNCL follows an autosomal recessive pattern of inheritance. Although over 50 mutations in this gene have been reported, 80–90% of patients with JNCL have a 1.02 kB deletion, resulting in a frameshift and prematurely truncated protein [2].

Children with JNCL usually present with vision impairment as the first reported symptom. The average age of onset ranges from 4–10 years [2]. Patients typically exhibit a rapidly progressive deterioration in vision, leading to legal blindness within 3 years, which is atypical when compared with other juvenile-onset maculopathies [3]. Other visual symptoms include esotropia, photophobia, nyctalopia, nystagmus, and dyschromatopsia [4]. Systemic features include seizures, behavioral abnormalities, motor dysfunction, impaired cognition, dementia, and premature death [3].

Fundoscopy may reveal a bull's-eye maculopathy, macular or peripheral pigmentary retinopathy, optic atrophy or optic disc pallor, bone-spicule pigment deposits, and arteriolar attenuation (Fig. 18.1a) [5]. Fundus autofluorescence may show abnormal macular hyperautofluorescence and peripheral hypoautofluorescence in areas of RPE atrophy (Fig. 18.1b). Goldmann visual fields may demonstrate scotomas or concentric constriction of peripheral fields.

Full-field electroretinogram (ERG) results are typically severely reduced or nonrecordable on initial presentation, or there may be a negative waveform present for the maximal/mixed response [4, 6]. Reduced cone flicker, non-recordable scotopic parameters, and normal responses have also been reported [6].

CLN3-related non-syndromic retinal degeneration follows an autosomal recessive pattern of inheritance. Patients display features more consistent with retinitis pigmentosa, with peripheral pigment mottling and ellipsoid zone loss outside the fovea on OCT [1]. One family with cone-rod degeneration has also been described [1].

Fig. 18.1 Case summary: 9-year-old male with Batten disease with *CLN3* mutations. **(a)** Wide-field color fundus photograph of the left eye showing RPE macular changes with scant bone spicule pigment deposition in the

mid-periphery. **(b)** Wide-field fundus autofluorescence of the left eye showing elevated abnormal parafoveal autofluorescence and hypoautofluorescence in areas of scant pigment deposition in the mid-periphery.

CLRN1 encodes Clarin-1, expressed in the ribbon synapses of the cochlea and retina. Although its function in the human retina is unknown, mutations in the gene are associated with Usher syndrome type 3A (USH3A) and non-syndromic retinitis pigmentosa/rod-cone dystrophy.

Mutations in *CLRN1* are associated with hearing loss and retinitis pigmentosa, with or without vestibular dysfunction. Patients with *CLRN1* mutations comprise a larger proportion of patients with Usher syndrome in Finnish and Ashkenazi Jewish populations due to founder effects [1, 2]. Individuals first present with bilateral sensorineural hearing impairment, which ranges from normal to moderate at younger ages and may be profound at later ages [3]. Onset is typically postlingual, and hearing loss is progressive, in contrast to other types of Usher syndrome [4]. Individuals present with visual symptoms, which include nyctalopia or constricted visual fields, from the first to sixth decade, with an average age of diagnosis of retinitis pigmentosa in the second decade [5]. Other visual symptoms include hyperopia, astigmatism, and cataracts. Individuals may have progressive loss of visual acuity with age-related severity similar to that of other types of Usher syndrome [3]. Fundoscopy may reveal features typical of retinitis pigmentosa, including peripheral bone spicule pigmentation, waxy

pallor of the optic disc, arteriole attenuation, and loss of retinal pigment epithelium (Figs. 19.1a and 19.2a) [6]. Optical coherence tomography (OCT) may show distorted foveal architecture, normal or reduced parafoveal retinal thickness, and disruption of the ellipsoid zone (more prominent outside the fovea), which tend to be worse in older patients (Figs. 19.1c and 19.2c) [6–8]. Near-infrared reduced-illuminance autofluorescence imaging may reveal a ring of parafoveal hyperautofluorescence (Figs. 19.1b and 19.2b) [6]. Full-field electroretinogram (ERG) is typically consistent with a rod-cone pattern of degeneration and may be non-recordable [6, 8]. GVF testing tends to show ring scotomas and progressive peripheral losses [8, 9]. Adaptive optics may reveal reduced photoreceptor densities in areas outside the fovea, and microperimetry may show elevated response thresholds, both of which tend to be more pronounced in advanced stages of disease [8].

CLRN1-related non-syndromic RP follows an autosomal recessive pattern of inheritance. Patients present with symptoms of RP without evidence of hearing loss/impairment. Fundoscopy may demonstrate typical findings of retinitis pigmentosa, such as arteriole attenuation, waxy disc pallor, and peripheral bone spicule pigmentation [10]. ERG may reveal a rod-cone pattern of degeneration [10].

Fig. 19.1 Case summary: 24-year-old male with RP and mild hearing loss since childhood. **(a)** Wide-field color fundus photograph of the right eye showing mid-peripheral RPE atrophy and bone spicule pigmentation. There is also RPE atrophy in the macula with peripapillary atrophy. **(b)** Wide-field fundus autofluorescence of the right eye show-

ing a faint ring of hyperautofluorescence surrounding the fovea and islands of hypoautofluorescence in areas of RPE atrophy in the mid-periphery and along the vascular arcades. **(c)** Spectral domain optical coherence tomography showing extrafoveal loss of the ellipsoid zone and outer nuclear layer.

Fig. 19.2 Case summary: 43-year-old female with Usher Syndrome. (a) Wide-field color fundus photograph of the right eye showing mid-peripheral RPE atrophy, scant bone spicule pigmentation, and a bull's-eye maculopathy with peripapillary atrophy. (b) Fundus autofluorescence of the right eye showing a ring of hypoautofluorescence surrounding the

fovea (corresponding to the bull's-eye lesion seen in Fig. 19.2a) and islands of hypoautofluorescence in areas of RPE atrophy in the mid-periphery. (c) Spectral domain optical coherence tomography showing extensive loss of the ellipsoid zone and outer nuclear layer with thinning of the RPE band surrounding the foveola.

CNGA3 encodes the alpha-subunit of the cone photoreceptor cGMP-gated channel involved in phototransduction. *CNGA3* mutations are associated with approximately 25% of autosomal recessive achromatopsia (rod monochromacy) [1–3]. Similarly to patients with mutations in *CNGB3*, patients with achromatopsia caused by mutations in *CNGA3* usually present in their first decade with poor visual acuity (20/200), photophobia, nonspecific color vision deficits, and nystagmus [4, 5]. VA remains stable in some patients but can also deteriorate with time. Fundoscopic examination usually reveals a normal fundus in childhood (60%), while adult patients tend to exhibit loss of foveal structure, pigmentary changes, or bull’s-eye

macular atrophy. Fundus autofluorescence may reveal foveal and parafoveal hyperfluorescence with normal cross-sectional retinal architecture on OCT in younger patients (Fig. 20.1). Older patients may exhibit focal foveal atrophy on FAF and OCT (Fig. 20.2). However, foveal abnormalities, such as hypolucency or loss of the ellipsoid zone, have also been reported in patients as young as 8 months of age [6]. The macular thickness is reduced, with the reduction typically resulting from outer retinal loss in the context of a maintained inner retina [6]. Electroretinography (ERG) usually shows diminished or absent photopic responses, while scotopic responses are usually normal [6, 7].

CNGB1 encodes one of the two subunits (the other is encoded by *CNGA1*) of the rod cyclic nucleotide-gated (CNG) channel. These CNG channels in the rod plasma membrane respond to light-mediated concentration changes in cGMP by causing an influx of calcium, creating calcium-gated voltage signals [1, 2]. Mutations in *CNGB1* cause autosomal recessive retinitis pigmentosa (RP) [1].

CNGB1 mutations are responsible for about 4% of autosomal recessive RP cases [1]. While Bareil et al. [3] described patients with *CNGB1* mutations as having a severe form of RP, others have described patients with *CNGB1* mutations as having less severe phenotypes, with later ages of onset of symptoms [4, 5]. As expected with RP, patients demonstrate night blindness, which may occur in early childhood [3], and a progressively restricted visual

field. Significantly reduced visual acuity or legal blindness has been noted in later adult years [4, 5]. Fundus exam, as expected for RP, reveals bony spicule-shaped pigment deposits (Fig. 21.1a, b) [3–5]. Fundus autofluorescence demonstrates hypoautofluorescence corresponding to the areas of atrophy and pigment deposition and may exhibit a hyperautofluorescent ring around the fovea (Fig. 21.1c, d). Optical coherence tomography shows the extent of photoreceptor loss, with progressive loss of the ellipsoid zone extending centrally from the periphery (Fig. 21.1e, f). ERG is eventually nonresponsive, but the age at which this is observed varies. Bareil et al. [3] noted a lack of rod response on ERG in his patient at age 30, while Bocquet et al. [4] noticed nonresponsive ERG at age 44 and Kondo et al. [5] at age 55.

Fig. 21.1 Case summary: 48-year-old female with autosomal recessive retinitis pigmentosa with homozygous mutations in *CNGB1* (c.2544dupG) with best-corrected visual acuity of 20/20 in both eyes that declined to 20/30 in the right eye and 20/40 in the left eye over the course of 3 years. (a, b) Color fundus photograph montages of the right and left eyes showing mid-peripheral bone spicule pigment deposits and RPE changes in the macula. (c, d) Fundus autofluorescence of the right and left eyes showing a hyperautofluorescent ring in the parafovea that gradually

shrinks over the course of 10 years (three panels show time points at 0, 5, and 10 years). There is also dense patchy hypoautofluorescence within an outside the arcades. As the hyperautofluorescent rings shrink with time, the areas surrounding the rings are gradually filled in by areas of hypoautofluorescence suggestive of atrophy. (e, f) Spectral domain optical coherence tomography of the right and left eyes showing progressive loss of the foveal ellipsoid zone in both eyes over the course of 6 years with the formation of a pseudo hole in the left eye.

CNGB3 encodes the beta-subunit of the cone photoreceptor cGMP-gated channel, which is involved in calcium influx during phototransduction. *CNGB3* mutations cause autosomal recessive achromatopsia (rod monochromatism), which usually presents in childhood, and cone dystrophy, which generally presents in young adulthood. *CNGB3* mutations are the most common cause (>50%) of achromatopsia [1].

Patients typically present in their first decade with poor visual acuity (20/100 to 20/200 or worse), photophobia, non-specific color vision deficits, and nystagmus. While it was widely believed that visual acuity remains stable in achromatopsia, many patients experience progressive loss of central vision [2, 3]. Young patients usually exhibit normal fundi (>60%), while older patients may show loss of the foveal structure, pigmentary changes, or bull's-eye macular atrophy (Figs. 22.1a, 22.2a) [4]. Fundus autofluorescence may reveal foveal and parafoveal hyperautofluorescence (Figs. 22.3, 22.1b) with normal cross-sectional retinal architecture on OCT in younger patients (Fig. 22.1c), which may be characteristic of achromatopsia. More advanced disease in older

patients may exhibit focal foveal atrophy and “punched-out” outer retinal cavitation on FAF and OCT (Fig. 22.2b, c). However, foveal abnormalities, such as hypolucency or loss of the ellipsoid zone, have also been reported in patients as young as 8 months old [5]. Macular thickness is reduced, with the reduction typically resulting from outer retinal loss in the context of a maintained inner retina [5]. Electroretinography (ERG) exhibits diminished or absent photopic responses, which show progressive loss in some patients [6]. Scotopic ERG responses are usually subnormal but generally do not decline over time [7].

Autosomal recessive cone dystrophy caused by mutations in *CNGB3* is characterized by progressive deterioration of visual acuity and abnormal color vision, which usually begin in the second decade of life [8]. Nystagmus is less common than in achromatopsia. Funduscopy findings are variable and may be normal or include RPE pigmentary changes or bull's-eye maculopathy. ERG reveals a characteristic progressive deterioration of photopic ERG parameters with scotopic parameters in the normal range [7].

CRB1 encodes a transmembrane protein involved in retinal development and organization. Mutations are responsible for Leber's congenital amaurosis (LCA) and retinitis pigmentosa (RP). *CRB1* has been reported to be associated with RP with retinal telangiectasias and exudation (Coats-like vasculopathy), RP with preservation of the para-arteriolar retinal pigment epithelium (PPRPE), and dominant pigmented paravenous chorioretinal atrophy [1–5].

LCA caused by *CRB1* mutations is characterized by visual dysfunction at a very young age [6]. Patients typically present before the age of 5 with visual acuities worse than 20/200, night blindness, photophobia, hyperopia, aberrant color vision, and nystagmus [4, 7, 8]. Keratoconus has also been reported in some studies [8, 9]. In the first 5 years, ERGs may be non-recordable or show a cone-rod or rod-cone pattern of dysfunction [10, 11]. Fundusoscopic and tomographic appearances may be variable, but certain features are suggestive of mutations in *CRB1* (Figs. 23.1a, 23.2, 23.3, 23.4, and 23.5),

including white dots at the RPE level in younger patients and mid-peripheral nummular pigmentation (Fig. 23.3) (also seen in patients with *NR2E3*, *NRL*, and *TULP1* mutations) in older patients [10]. Macular atrophy has been reported in about 50% of patients in some studies. OCT may show intraretinal cystic spaces, cystoid macular edema, or an overall increase in foveal thickness (Fig. 23.4b) [10]; Jacobson et al. [12] have reported thick unlaminate retinal architecture in LCA patients with *CRB1* mutations. The most common mutation, C948Y, has been reported to result in LCA when in a homozygous state and to be more likely to be associated with RP when in a compound heterozygous state with another missense allele (Fig. 23.3) [3, 4]. However, another study was unable to recapitulate these findings, though they did report that LCA was more commonly associated with one or two null alleles [2]. Fundus autofluorescence may show loss of autofluorescence signal in areas of retinal pigment epithelium atrophy (Figs. 23.1b and 23.5b).

Fig. 23.1 Case summary: An 8-year-old boy with Leber's congenital amaurosis (LCA). **(a)** Color fundus photograph of the right eye showing diffuse retinal pigment epithelium (RPE) atrophy within and outside the vascular arcades associated with pigmentary changes and

peripapillary atrophy. **(b)** Fundus autofluorescence of the right eye showing diffuse loss of autofluorescence, with focal pinpoint areas of autofluorescence throughout the fundus.

Fig. 23.2 Color fundus photograph of the right eye from a 31-year-old woman with LCA, showing diffuse RPE atrophy with dense bone-spicule pigment deposits throughout the posterior pole.

Fig. 23.3 Color fundus photograph of the right eye from an 18-year-old man with rod-cone dystrophy (retinitis pigmentosa), showing RPE atrophy outside the arcades with sparse pigment deposits.

Fig. 23.4 Color fundus photograph of the right eye from a 28-year-old man, showing nummular pigment deposits with diffuse RPE and macular atrophy with peripapillary atrophy.

Up to 7% of recessive RP is caused by mutations in *CRB1* [13]. Patients usually present in the second decade of life with night blindness and reduced visual acuity (ranging from 20/50 to LP in some studies), though in some patients, central visual deficits and photosensitivity predominate. Hyperopia is often observed, while nystagmus is uncommon. These patients often exhibit a variable fundusoscopic phenotype, with both bone-spicule pattern or clumped nummular pigmentary deposits possible (Figs. 23.3, 23.4, 23.5a, and 23.6). Other findings with *CRB1* include PPRPE and Coats-like vasculopathy, which are commonly observed in the context of RP [2, 3, 5, 15, 16]. Most patients exhibit a maculopathy, with up to 50% of patients exhibiting CME (Fig. 23.5b) [2]. Some patients have been reported to develop angle-closure glaucoma and pupillary block as a result of peripheral telangiectasias [10]. Nanophthalmos with RP has been reported [14].

Dominantly inherited pigmented paravenous chorioretinal atrophy has also been reported to be associated with mutations in *CRB1* [17]. McKay et al. [17] reported that the

Fig. 23.5 Case summary: 8-year-old female (CEI28492) with Leber's congenital amaurosis/Severe Early Childhood Onset Retinal Dystrophy (SECORD) with heterozygous mutations in *CRB1*. (a) Wide-field color fundus photograph of the left eye showing RPE atrophy with pigmen-

tary changes along the arcades. (b) Spectral-domain optical coherence tomography showing extensive loss of the ellipsoid zone with foveal-sparing and cystoid macular edema.

Fig. 23.6 Case summary: 6-year-old female (CEI26281) with Leber's congenital amaurosis/Severe Early Childhood Onset Retinal Dystrophy (SECORD) with compound heterozygous mutations in *CRB1*. (a) Color fundus photograph of the left eye showing RPE

atrophy with pigmentary changes along the arcades. (b) Wide-field fundus autofluorescence of the right eye showing dense and confluent dropout of autofluorescence signal in the posterior pole, suggestive of RPE atrophy.

initial sign of this disease was symmetric chorioretinal atrophy, which progressed to paravenous pigmentation that begins peripherally and extends centrally.

CRX encodes a transcription factor involved in the differentiation of photoreceptor cells. Mutations are responsible for autosomal dominant cone-rod dystrophy, adult-onset dominant retinitis pigmentosa (RP), and Leber's congenital amaurosis (LCA) [1–5].

CRX mutations are responsible for about 5% of cone-rod dystrophy [3, 4, 6]. Patients typically present in the first-to-third decades of life with progressively worsening visual acuity (20/25 to <20/200), poor color vision, and, commonly, nystagmus, photosensitivity, and hyperopia. Patients with certain mutations may have a later onset of visual acuity loss [7]. Night blindness and loss of peripheral vision typically occur later in the disease course. Fundus examination is characterized by progressive maculopathy, ranging from normal to pigment clumping in young patients to choroidal and retinal pigment epithelium (RPE) atrophy in later stages of disease, vessel attenuation, and variable pigment deposition peripherally (Figs. 24.1 and 24.2a) [8]. Fundus autofluorescence (FAF) may reveal macular atrophy and a peri-foveal hyperfluorescent ring (Fig. 24.2b). A progressively deteriorating cone-rod electroretinogram pattern (ERG) pattern is characteristic, with initial cone abnormalities progressing to panretinal dysfunction; one study has also reported a negative ERG in one family [9]. Goldmann visual field typically

reveals central scotomata with peripherally constricted fields.

CRX mutations are also responsible for about 3% of LCA, most often in an autosomal dominant manner [6, 10]. Patients present at birth or within the first year of life with visual abnormalities (such as poor visual pursuit and digital ocular signs), nystagmus, and a non-recordable ERG [2, 5]. Even when vision is maintained, visual acuity is usually no better than 20/200; night blindness and hyperopia are very common [11, 12]. Fundus examination may be normal initially (Fig. 24.3) but often exhibits features of retinal degeneration, such as macular atrophy, vessel attenuation, and peripheral bone-spicule pigment deposits [11]. Visual improvement has been reported in one case [13]. Autosomal recessive inheritance has also been reported in one family [14].

About 1% of retinitis pigmentosa is attributable to mutations in *CRX* [5, 6]. These patients may be asymptomatic until their 50s to 60s, when they present with peripheral visual defects that deteriorate over the course of a decade. Central visual acuity and ERG parameters are generally maintained until late in the disease course. Fundus features may mimic classical RP and contain pigmentary clumping in the periphery with no macular changes. ERG and GVF typically reveal a rod-cone pattern of retinal degeneration.

C1QTNF5 (previously called *CTRP5*) encodes C1q tumor necrosis factor-related protein and is highly expressed in the retinal pigment epithelium (RPE), lens, and ciliary epithelium. *C1QTNF5* plays an important role in the adhesion of the RPE to the Bruch Membrane, and mutations are thought to impair the adhesion, resulting in sub-RPE deposits. Mutations in *C1QTNF5* are associated with late-onset retinal degeneration (LORD).

C1QTNF5-related LORD follows an autosomal dominant pattern of inheritance. Patients with LORD usually experience a late onset of nyctalopia in the fourth to the sixth decades of life [1]. Best-corrected visual acuity may initially be normal and tends to worsen throughout the disease process to as low as 20/400 [2]. There may be color vision abnormalities. Goldmann visual fields are typically normal early in life and tend to exhibit nasal field loss prior to deficits in the temporal field. Some patients experience central vision loss late in the disease process, usually in their 60s [1]. Choroidal neovascular membrane associated with areas of atrophy may develop late in the disease [1, 3]. Many older patients have ocular hypertension/open-angle glaucoma, though it is unclear whether this is related to the elongated anterior lens zonules [3]. Characteristic ophthalmic findings include peripupillary iris atrophy and elongated anterior lens

zonule insertions (Fig. 25.1e) [1–4]. Drusen deposits in the mid- and far-retinal periphery are also common early in the disease process, though the fundus may be normal, and many patients are asymptomatic at this early stage (Fig. 25.1a, b) [3, 4]. Some patients develop scalloped chorioretinal atrophy and bony spicule pigmentary changes in late stages (Fig. 25.2) [1]. Fundus autofluorescence (FAF) imaging may exhibit areas of hypoautofluorescence associated with regions of chorioretinal atrophy, with a surrounding hyperautofluorescent border (Fig. 25.1c) [1, 2]. Similar to other retinal degenerations, spectral domain optical coherence tomography (SD-OCT) may reveal widespread loss of the outer retinal layers, with areas of absence of the ellipsoid zone suggestive of photoreceptor loss and thinning of the outer nuclear layer [1]. Hyper-reflective deposits may be present in the RPE-Bruch's membrane complex, with some patients exhibiting areas of separation in this complex (Fig. 25.1d); choroidal thinning may also be observed [1, 2]. Electroretinography (ERG) may be normal early in the disease state but typically exhibits a rod-cone pattern of degeneration [1, 2]. Pattern or multi-focal ERG may display significant macular involvement in some patients [1]. Abnormal dark adaptation may be found early, up to a decade before ophthalmic signs of LORD are exhibited [1, 3].

CYP4V2 encodes cytochrome P450 4V2, an enzyme responsible for the oxidation of intermediates in the metabolic breakdown of fatty acids. Mutations in *CYP4V2* are associated with Bietti Crystalline Dystrophy (BCD) [1].

BCD follows an autosomal recessive pattern of inheritance, with an onset typically in the second-to-fourth decades of life. The presenting symptoms are variable, but patients experience reduced visual acuity, progressive nyctalopia, visual field constriction, and dyschromatopsia. BCVAs vary widely but tend to worsen with age [2]. Small crystalline deposits may be observed in the peripheral cornea with slit-lamp biomicroscopy (similar crystals may also be seen in peripheral lymphocytes). Fundoscopy reveals crystals in the posterior pole (sometimes extending to the mid-periphery)

associated with chorioretinal atrophy (Figs. 26.1a, b and 26.2a) [3]. The crystals, usually in areas of mild degeneration, are less pronounced in areas of chorioretinal atrophy in advanced stages of disease [2, 4, 5]. The crystals localize adjacent to the inner side of retinal pigment epithelium and can be better visualized with SD-OCT (Fig. 26.2b) [6]. Foveal thinning and interruptions in the ellipsoid band may also be seen, with a preservation of the external limiting membrane. In areas of RPE atrophy, presumed photoreceptor rosettes may be observed at the level of Bruch's membrane [2, 4, 6]. ERGs in BCD patients are usually diminished and reflect the severity of the chorioretinal degeneration, ranging from normal to non-recordable photopic and scotopic parameters [7, 8].

Fig. 26.1 Case summary: 44-year-old man with BCD. (a) Color fundus photograph of the left eye, showing chorioretinal atrophy involving the macula and peripapillary regions and crystalline deposits in the macula and along and outside the vascular arcades. (b) Fluorescein

angiography of the left eye showing severe retinal pigment epithelial and choroidal atrophy, permitting easy visualization of the deep choroidal vasculature.

Fig. 26.2 Case summary: 43-year-old male with BCD (CEI25442). (a) Color fundus photograph of the right eye, showing chorioretinal atrophy along the arcades and in the macula (sparing the fovea), with scattered crystalline deposits. (b) Spectral domain optical coherence

tomography of the right eye, showing extrafoveal RPE, ellipsoid zone and outer nuclear layer loss, with hyper-reflective deposits at the level of the RPE (at the outer nuclear layer as well as in the inner retina).

DHDDS encodes dehydrodolichyl diphosphate synthase, an enzyme expressed in many tissues, which catalyzes the production of dolichol, which is a glycosyl carrier lipid required for the synthesis of many types of glycoproteins. Autosomal recessive mutations in *DHDDS* cause retinitis pigmentosa (RP; rod-cone dystrophy). A founder mutation has been described in the Ashkenazi Jewish population, which may account for over 10% of recessive retinitis pigmentosa in this community [1, 2]. Patients tend to exhibit typical RP symptoms with a teenage onset of nyctalopia and peripheral vision loss. Visual acuities may vary widely but tends to be better in younger patients [2]. The rate of disease progression may vary; some patients decline to light perception visual acuity within a decade after exhibiting a non-recordable ERG in their late teens [3]. Fundus findings include characteristic RP findings, such as waxy optic nerve pallor, arteriolar attenuation, and bone spicule-pigment deposition. Macular atrophy

has been reported in some patients [2]. Optical coherence tomography (OCT) may reveal preservation of retinal thickness and the photoreceptors at the fovea, which tends to become thinner with increased eccentricity. Some patients exhibit cystoid macular edema [2]. Near-infrared autofluorescence imaging reveals islands of residual retinal pigment epithelium that correspond to areas of preserved photoreceptors visualized on OCT. The electroretinogram usually shows a rod-cone pattern of degeneration, while Goldmann visual field reveals peripheral visual field loss with central islands remaining in older patients [2]. Likewise, dark-adapted static perimetry reveals loss of rod function with age [2].

The chain length of dolichol in plasma and urine have been shown to be altered in patients carrying *DHDDS* mutations [4]. The pathophysiology of retinal dysfunction is not fully understood, but knock-down studies in zebra fish result in photoreceptor degeneration [5].

Fig. 27.1 Case summary: 41 year old man with retinitis pigmentosa. Color photo of the right eye, showing optic disc pallor, vascular attenuation, diffuse retinal atrophy, and peripheral bone spicules.

Mutations in *EFEMP1*, which encodes a retinal pigment epithelium (RPE) extracellular matrix glycoprotein of uncertain function, cause autosomal dominant drusen (Doyme's Honeycomb Dystrophy, Malattia Leventinese) [1, 2].

Patients usually present in their 40s to 50s with reduced central acuity and delayed dark adaptation, although many patients are asymptomatic. The rate of visual acuity (VA) deterioration varies, with some patients remaining stable over the course of a decade and others experiencing significant loss of VA. Progressive macular atrophy is the primary cause of vision loss, though choroidal neovascularization is a rare complication that may cause rapid vision loss (Fig. 28.1b). Fundus examination is characterized by bilateral soft drusen throughout the macula, including nasal to the optic disc, which can become confluent (which may give the appearance of retinal fibrosis) and develop into

areas of atrophy later in the disease course. The drusen are classically in a radial pattern in the maculae of both eyes (Figs. 28.1a and 28.2a). There are often interocular differences in VA and fundus appearance, but both eyes are almost always affected. The characteristics of the drusen exhibit significant intra- and interfamilial phenotypic variability, but they are typically absent in the periphery. Certain genotypes (e.g., R345W) [3] consistently exhibit peripapillary drusen. Fundus autofluorescence shows hyperautofluorescence in areas of drusen accumulation, while hypofluorescence corresponds to areas of atrophy in later stages of disease. Optical coherence tomography is helpful in imaging the extent and features of the drusen and may also show features of neovascularization. Nonpenetration of disease has been reported in one patient with an R345W mutation [3].

Fig. 28.1 Case summary: 51-year old woman with dominant drusen. (a) Color fundus photograph of the right eye showing drusen in a classical radial orientation in the macula. (b) Fluorescein angiography of

the right eye showing staining of the drusen and a choroidal neovascular membrane in the nasal macula.

Fig. 28.2 OCT shows extensive drusenoid deposits classical of this condition. Case summary: 27-year-old man. (a) Color fundus photograph of the right eye showing drusen in a classical radial orientation in the macula, with hyperpigmentation in areas suggestive of scarring.

Also visible are drusen nasal to the optic disc. (b) Spectral-domain optical coherence tomography showing extensive macular drusen appearing to be between the retinal pigment epithelium and Bruch's membrane.

Mutations in *ELOVL4*, which is required for the synthesis of fatty acids, cause an autosomal dominant macular dystrophy, also known as “Stargardt-like macular dystrophy” [1–4].

Patients usually present with reduced visual acuity (ranging from 20/50 to 20/200 or worse) as early as the second decade of life, but onset can occur as late as the fifth decade [5]. Patients tend to lose visual acuity with age; color and peripheral vision are usually normal. Fundus examination may be characterized by macular flecks and atrophy similar to those seen in *ABCA4*-related disease, with a normal

peripheral retina. However, fundus appearance may exhibit intra- and interfamilial variability, and patients may exhibit macular atrophy with or without flecks, subtle macular retinal pigment epithelium (RPE) disruption, or pattern dystrophy. Full field electroretinography (ERG) is usually normal or mildly decreased, while multifocal ERGs are abnormal. Fluorescein angiography may show macular window defects but has not been reported to exhibit the “dark choroid” characteristic of *ABCA4*-related disease (Fig. 29.1) [5].

Fig. 29.1 Color fundus photograph from a 21-year-old man, showing subtle macular retinal pigment epithelium disruption.

Mutations in *EYS*, which encodes a protein important for photoreceptor morphology, are a common cause of autosomal recessive retinitis pigmentosa (rod-cone dystrophy) and rarely cone-rod dystrophy [1–9]. Patients may present as early as their teens or as late as their forties with night blindness and progressive loss of peripheral field. Visual acuity is usually maintained until late in the disease (often better than 20/50) and funduscopy reveals optic disc pallor, bone-spicule pigment deposits in the mid-periphery to periphery that increase in density with age, and attenuated vessels. Cataracts have been reported to occur at a younger age (average of 50 years in one study) (Figs. 30.1a and 30.2a) [7]. GVF reveals a rod-cone pattern with progressively constricting fields (Fig. 30.1b), and ERG reveals a rod-cone pattern of degeneration (Fig. 30.1c). One study has shown that patients with homozygous mutations in *EYS*

tend to deteriorate with respect to visual acuity and visual fields more rapidly than patients who are compound heterozygotes for pathogenic mutations at the *EYS* locus [7]. Fundus autofluorescence may show hypoautofluorescence in areas of atrophy or hyperautofluorescence at the interface between atrophic and residual (but dysfunctional) retina (Fig. 30.2b). Spectral domain optical coherence tomography may help delineate areas of residual photoreceptor and retinal pigment epithelium (RPE) loss (Fig. 30.2c).

Phenotypic variability has been reported in *EYS* mutations; some patients present with photophobia, night blindness, and reduced visual acuity earlier in the disease course [4]. These patients may exhibit RPE changes or macular atrophy on funduscopy, central scotomata on GVF, and a cone-rod pattern of dysfunction on ERG testing.

Fig. 30.1 Case summary: 34-year-old man with rod-cone dystrophy with mutations in *EYS*. Color fundus photographs of the left eye at age 34 (left), showing midperipheral RPE atrophy and bone-spicule pig-

ment deposits. Wide-field photograph 7 years later (right), showing an increased density of pigment deposits.

Fig. 30.2 Case summary: 58-year-old male with *EYS* mutations and rod-cone dystrophy. (a) Color fundus photograph (montage) of the left eye, showing optic nerve waxy pallor, retinal vessel attenuation, RPE atrophy along the arcades, and dense mid-peripheral bone spicule pigment deposits. (b) Fundus autofluorescence of the left eye, showing dense hypoautofluorescence at and outside the arcades corresponding

to RPE atrophy and pigmentation. There is hyperautofluorescence at the interface between central residual autofluorescent signal and peripheral hypoautofluorescence. (c) Spectral domain optical coherence tomography of the left eye, showing dense ellipsoid zone loss at the macula with a residual central island at the foveola. There are also focal areas of RPE atrophy/loss.

FAM161A encodes a ciliary protein that appears to be involved in microtubule stabilization/transport. Mutations in *FAM161A* have been associated with autosomal recessive retinitis pigmentosa (RP) [1–3].

Limited literature is available on patients with mutations in *FAM161A*, but most present with the features of typical RP, although visual acuity may be worse than other mutations. Patients with *FAM161A*-related RP have varying ages of onset, typically from their first-to-third decades of life. Myopia and low visual acuities (ranging from no light perception to 20/200) are common, with count fingers acuity reported as young as age 15. Younger patients in their second decade of life may have better visual acuities, which tends to decline to severe visual handicap by the third and

fourth decades of life. Fundoscopy may reveal typical features of retinitis pigmentosa, with arteriole attenuation, bone spicule pigment deposits, waxy optic disc pallor, cataracts, and optic atrophy [2]. There may be grayish dots extending from the arcades to the periphery. OCT imaging shows thinning of the outer nuclear layer with relative preservation under the fovea and may demonstrate the subretinal depositis (Fig. 31.1) [3]. Fundus autofluorescence (FAF) imaging may reveal a ring of hyperautofluorescence around the fovea. Full-field ERGs usually exhibit significantly reduced cone and rod responses and are often non-recordable, though some patients retain residual cone function at earlier ages [1–3]. GVF typically reveals progressive peripheral field loss [3].

Fig. 31.1 Spectral domain optical coherence tomography of the right eye from a 55-year-old woman with typical RP and gray dots extending from the mid-periphery. There is extensive loss of the ellipsoid zone

(EZ) and outer nuclear layer (ONL), with central foveal sparing. Subretinal deposits are also visible the areas of EZ/ONL loss.

GNAT1 (Guanine nucleotide-binding protein, alpha-transducing activity polypeptide 1) encodes the alpha subunit of rod transducin. Transducin is the G-protein involved in the phototransduction cascade that facilitates the interaction between rhodopsin and cGMP. Mutations in *GNAT1* have been shown to cause both autosomal recessive and autosomal dominant forms of congenital stationary night blindness (CSNB) and autosomal recessive rod-cone dystrophy [1, 2].

Autosomal dominant CSNB may show non-progressive night blindness from early infancy. Myopia is common, while visual acuities and color vision are typically within normal limits. GVF and fundus appearance are typically normal. The Nougaret type of CSNB, based on the pedigree of Jean Nougaret, demonstrates an electroretinogram (ERG) abnormality in which the rod a-wave is missing [2]. In contrast, a Riggs-type ERG pattern reveals an absent b-wave in response to flashes of dim light and a cone-like response to bright light in scotopic testing conditions. Light-adapted states are typically normal. Dark adaptation testing reveals reduction in rod sensitivities in most patients. Some studies have suggested that these ERG findings reflect a presynaptic defect in rod phototransduction in patients with CSNB [3].

Autosomal recessive CSNB has been reported in one study of a consanguineous family that had many affected family members. Night blindness may start from early childhood, with unaffected visual acuity and color vision. Fundus findings are typically normal, with no signs of arteriolar attenuation or bone spicule changes. ERG recordings may reveal nearly absent a- and b-waves in scotopic conditions with normal photopic parameters [1].

There are a few case reports of patients with homozygous *GNAT1* pathogenic variants associated with late-onset rod-cone dystrophy.

GNAT2 encodes guanine nucleotide-binding protein G(t) subunit alpha-2, which is a part of the transducin complex that amplifies and transmits the visual signal in cone photoreceptors. Autosomal recessive mutations in *GNAT2* cause approximately 1–2% of achromatopsia [1, 2]. Patients with *GNAT2*-related achromatopsia exhibit nystagmus beginning in early infancy, photophobia, abnormal color vision, and poor visual acuity (VA) (usually worse than 20/200–20/400). Progressive deterioration of VA may be observed, while nystagmus may improve in some patients [3]. Color vision testing is usually abnormal, with rod monochromacy observed in many patients, although some patients may retain some

color vision [3–5]. One study has suggested that the retention of color vision may be related to splice site mutations that sometimes result in functional protein product [5]. Fundoscopy usually reveals a normal retinal appearance, though some patients exhibit an abnormal foveal reflex or atrophy (Fig. 33.1a–d) [3]. Full-field ERG testing typically reveals varying degrees of abnormal cone function along with normal rod function, although scotopic a-wave amplitudes are reduced in some patients [3–5]. Microperimetry may show central scotomas; SD-OCT usually reveals well-maintained foveal architecture without hypoplasia but may exhibit a hyporeflective zone at the fovea (Fig. 33.1e–f) [6].

GPR98 encodes G-protein coupled receptor 98, which is expressed broadly in human cells. Autosomal recessive mutations in *GPR98* cause Usher syndrome type 2C, which is characterized by congenital sensorineural hearing loss and retinitis pigmentosa. These patients tend to exhibit bilateral mild-to-moderate hearing impairment with a downward sloping audiogram, demonstrating more loss at higher frequencies [1, 2]. Visual acuity is maintained until later in the disease course, while nyctalopia and peripheral vision loss typically present between the second and third decades of life [2, 3]. Goldmann visual fields reveal progressive peripheral constriction [2, 4]. Color-vision testing may reveal errors in the Tritan axis [4]. Early-onset bilateral cataracts are also common, although specific subtypes of cataracts have not been described in the literature [2]. Fundoscopy reveals typical findings of retinitis pigmentosa, including bone spicule pigment deposits from the mid-periphery to the periphery, attenuated retinal vascula-

ture, optic nerve pallor, and RPE atrophy; maculopathy is less commonly observed (Figs. 34.1a, 34.2, 34.3 and 34.4) [3, 4]. Fundus autofluorescence reveals hypoautofluorescence in areas corresponding to atrophy, with some patients exhibiting a ring of macular hyperfluorescence (Fig. 34.1b) [4]. Some patients may have cystoid macular edema; patients with normal OCT architecture tend to exhibit a wide range of visual acuity [5]. Increased inner retinal thickness has also been reported in one family [1]. Full-field electroretinography (ERG) tends to reveal a rod-cone pattern of degeneration and is often non-recordable by the fourth decade of life; multifocal ERG tends to reveal maintained function at the macula [1, 4, 5]. There have been two patients reported to exhibit a cone dystrophy on ERG examination in the context of a fundus resembling classical retinitis pigmentosa [1].

Mutations in *GPR98* have also been associated with a subtype of childhood seizures [6].

GUCA1A encodes guanylate cyclase-activating protein 1A (GCAP1), which is a calcium-binding protein located within the inner segments of the photoreceptors. It regulates guanylate cyclase 1 by sensing calcium concentrations, which is important for the recovery of rod photoreceptors after light exposure and for the overall phototransduction cascade. Mutations in *GUCA1A* cause autosomal dominant cone and cone-rod dystrophy [1–4].

Onset of visual symptoms for *GUCA1A*-related autosomal dominant cone dystrophy generally occurs after the first two decades of life, between the 20s and 50s. Initial symptoms include reduced visual acuity, loss of color vision, and mild photophobia. Nystagmus is uncommon. Visual acuity usually deteriorates to between 20/200 and count fingers. A range of macular phenotypes may be observed; changes at the level of the retinal pigment epithelium (RPE) at the macula may be observed prior to vision loss. Funduscopic changes are minimal at an early age but may consist of subtle granularity of the RPE. Older patients may exhibit macular atrophy, bone-spicule like pigmentation, and retinal vascular attenuation. Goldmann Visual Fields (GVF) reveal full peripheral fields with central scotomas. Full-field electroretinography (ERG) exhibits significant loss of cone function over time, usually in the context of normal rod parameters [1–7]. Some patients may exhibit rod abnormalities later in life. Intra-familial variability has been shown in some studies, with members of some families exhibiting symptoms of cone-rod dystrophy while others exhibit isolated macular dysfunction [3, 4].

Patients with cone-rod dystrophy experience similar symptoms to cone dystrophy patients but are more likely to experience nyctalopia and peripheral vision loss earlier in the disease process. In one study, symptoms (photophobia,

poor acuity) were seen within the first decade in a Chinese family. Full-field ERG in these patients revealed a cone-rod pattern of degeneration. Fundus examination may reveal optic disc pallor, attenuated retinal arterioles, macular atrophy, or pigmentary changes in the macula [7, 8].

GUCA1B encodes guanylate cyclase activator 1b, which is a calcium-binding protein required for the stimulation of guanylate cyclases in photoreceptors. It is particularly important for rod recovery after light exposure [1]. Mutations in *GUCA1B* cause retinitis pigmentosa (RP).

GUCA1B-related RP follows an autosomal dominant pattern of inheritance. Patients usually have typical features corresponding to RP. Visual acuities may vary from 20/20 to 20/200, with a decline over the course of disease progression; acuity is usually maintained until late in the disease course. Fundoscopy may reveal variable distribution of pigmentary deposition, ranging from the mid-periphery to more diffuse deposition; some patients have been reported to exhibit signs of macular pigment deposition and atrophy [2]. Electroretinogram (ERG) findings may demonstrate severe deterioration of both rod and cone function, with greatly reduced or nonrecordable photopic and scotopic amplitudes

[2]. Goldmann Visual Fields (GVF) usually reveal a rod-cone pattern of field loss (progressive visual field constriction). There may be significant intrafamilial variability; some patients with disease-causing mutations have been reported to be asymptomatic and to exhibit a normal fundus [2].

GUCY2D encodes guanylyl cyclase 1, which is an enzyme with unknown function expressed in rod and cone photoreceptors. Mutations in *GUCY2D* are associated with autosomal recessive Leber congenital amaurosis (LCA), autosomal recessive cone-rod dystrophy (CORD), and autosomal dominant cone dystrophy (COD).

LCA may be caused by autosomal recessive mutations in *GUCY2D*. These patients usually exhibit nystagmus and nonrecordable ERGs within the first months of life, in addition to other findings in LCA such as poor pursuit and oculodigital sign [1]. Within the first 2 years of life, photophobia and hypermetropia greater than +7.00 D are commonly observed, and visual acuities typically range from count fingers to light perception [1]. Keratoconus may be observed in some patients, possibly secondary to chronic rubbing of the eyes [2]. Fundus examination can appear completely normal or display a “salt-and-pepper” appearance [2]. Older patients have been reported to exhibit early degeneration of the macular and peripheral retina, but it is unclear when this begins to develop and whether it always progresses from an earlier “salt-and-pepper” appearance [1]. Though published data is limited, some patients may exhibit relatively normal FAF imaging in the context of abnormal retinal lamination with normal macular thickness on time-domain OCT [2].

Recessive mutations may also result in a cone-rod dystrophy phenotype [3]. While age of onset may vary, these patients present with nyctalopia in addition to poor visual acuity, dyschromatopsia, and photophobia [3]. In contrast to patients with LCA, these patients tend to retain functional vision during childhood. Fundoscopy may reveal bone spicule pigment deposits, optic disc pallor, and retinal arteriolar attenuation in the context of macular atrophy [3]. Goldmann visual field testing may reveal central scotomas within the first decade of life [4]. Electroretinography (ERG) tends to reveal reduced photopic and scotopic parameters [3, 4].

GUCY2D-related COD typically follows an autosomal dominant pattern of inheritance. Most patients have an onset of photophobia and bilateral visual acuity impairment

within the first decade of life. Visual acuities are abnormal at presentation but vary widely from patient to patient, tend to decline with time, and are often less than 20/200 by the third decade of life. Nyctalopia is uncommon in this disease entity, while dyschromatopsia is commonly observed [5, 6]. In children less than 5 years of age, fundus findings may reveal optic disc pallor, macular white deposits, and granular RPE [5]. Fundus findings in adults are typified by macular atrophy, which is often well-defined [7]. Younger patients exhibit pigment mottling in the macula prior to developing perifoveal atrophy [8]. FAF imaging may reveal a ring of hyperautofluorescence surrounding a region of speckled macular hypoautofluorescence [8]. Full-field ERG is characterized by abnormal photopic parameters with normal scotopic function [5, 7]. GVF reveals central scotomas with full peripheral fields [7]. OCT may reveal a foveal loss of the ellipsoid zone early in the disease process, which progresses to retinal thinning [2, 8]. Incomplete penetrance is possible; some patients within the same family and carrying the same disease-causing mutation may not experience symptoms or exhibit any signs of disease [7]. Certain dominantly-inherited mutations of *GUCY2D* have also been reported in families with a central areolar choroidal dystrophy (CACD) phenotype [9].

Cone-rod dystrophies have also been described in patients with autosomal dominant inheritance, although they may be part of the cone dystrophy spectrum described above (Fig. 37.1a) [4, 10, 11]. Notable differences in these patients include the fact that loss of peripheral visual fields is more common, and not all patients experience nyctalopia [10]. While visual acuity may be relatively maintained during the teenage years, most patients have visual acuity worse than 20/200 by age 40; myopia has been reported in 62% of patients in one family [11]. Dark adaptation thresholds are elevated, and some patients may exhibit a negative ERG in the context of both rod and cone ERG abnormalities; multifocal ERG reveals reduced central responses [10]. FAF imaging tends to reveal hypoautofluorescence at the macula in areas of atrophy with a surrounding area of hyperautofluo-

Fig. 37.1 Case summary: 63-year-old female (CEI16027, courtesy of Dr. Richard Weleber) with autosomal dominant cone-rod dystrophy with heterozygous missense mutations in *GUCY2D*. **(a)** Wide-field color fundus photograph of the right eye, showing peripheral retinal pigment epithelium atrophy (with a choroideremia-like appearance of

the periphery) as well as central macular atrophy. **(b)** Wide-field fundus autofluorescence, showing central macular hypofluorescence corresponding to RPE atrophy, with a surrounding ring of hyperautofluorescence.

rescence, similar to *GUCY2D*-associated cone dystrophy (Fig. 37.1b). OCT findings range from photoreceptor layer thinning with a maintained ellipsoid zone to a punched out localized cavitation with loss of the ellipsoid zone at the fovea [10].

IMPDH1 (RP10) encodes inosine-5-prime-monophosphate dehydrogenase, which plays a key role in the purine biosynthesis pathway. Mutations in *IMPDH1* cause 2–3% of dominant retinitis pigmentosa (ADRP) (rod-cone dystrophy) and rarely cause Leber congenital amaurosis (LCA) [1–8]. While *IMPDH1* is a ubiquitously expressed gene, retina-specific isoforms may be responsible for a phenotype limited to retinal degeneration [9–11].

Patients with ADRP caused by mutations in *IMPDH1* present between the first and third decades of life with night blindness and/or peripheral field loss that progress with time. There is often variability in age of onset even in patients with the same mutations, and symptoms may begin as late as in life as the 40s [3]. Visual acuity may be maintained until later in the disease course but has been shown to be severely reduced at an early age in some patients [6, 12, 13]. Some patients may have color vision deficits [13]. Early-onset posterior subcapsular cataracts are common (average onset of 34 years in one study [5]) [3]. Patients with *IMPDH1* mutations present with typical fundus findings of RP, such as mid-peripheral to peripheral bone-spicule pigment deposits, optic disc pallor, and retinal vessel attenuation; pigmented cells in the vitreous may also be observed (Figs. 38.1a and 38.3). Some patients may develop CME or subretinal fluid, best visualized with OCT [3, 13, 14]. Peripheral/mid-peripheral RPE atrophy develops over time (Figs. 38.1a, 38.2, and 38.3). Some patients develop bull's-eye macular atrophy as well,

though this is less commonly observed (Fig. 38.2) [2]. Most patients exhibit cataracts and pigment deposits after the middle of the third decade of life [3]. Fundus autofluorescence shows hypoautofluorescence in areas of RPE atrophy (Fig. 38.1b). The full-field ERG is severely reduced, usually to a similar extent for both rod and cone parameters, but may be recordable in a rod-cone pattern in some younger patients [3, 5, 13, 14]. Multifocal ERG generally shows maintenance of central cone responses, which may be lost with time [14]. Dark adaptation thresholds are frequently elevated. GVF reveals severe progressive constriction of the visual field (Fig. 38.1c) [13].

Some mutations in *IMPDH1* have been associated with dominant LCA (e.g., Arg105Trp and Asn198Lys) [2]. One of these patients presented with roving nystagmus with absent fixation to light before age 1, with a mottled-appearing fundus without pigmentary changes. The other patient presented at about 3 years of age with peripheral vision loss, though her central vision was maintained at 20/40 bilaterally. The fundus of the 3-year-old revealed optic disc pallor, diffuse depigmentation of the fundus, and attenuated retinal vessels. More recently, an additional patient with autosomal recessive *IMPDH1*-associated disease presenting within the first few months of life with poor vision and nystagmus [15]. This patient had LP visual acuity and exhibited attenuated retinal vasculature, macular atrophy and pigment deposits in the fundus, and a non-recordable full-field ERG when evaluated at age 23.

Fig. 38.1 Case summary: 19-year-old woman with rod-cone dystrophy. (a) Wide-field color fundus photograph of the right eye, showing typical findings of rod-cone dystrophy, including mid-periphery RPE atrophy with bone spicule pigmentation and sparing of the macula. (b) Wide-field fundus autofluorescence of the right eye, showing loss of

mid-peripheral autofluorescence in areas with RPE atrophy, with relatively normal appearing macular autofluorescence. (c) Goldmann visual field of the right eye, showing constricted fields in all isopters, suggestive of a rod-cone pattern of visual field loss.

Fig. 38.2 Wide-field color fundus photograph of the left eye from a 56-year-old male with rod-cone dystrophy with a bull's eye lesion in the macula and dense mid-peripheral bone spicule pigment deposits.

Fig. 38.3 Color fundus photograph from a 20-year-old male (CEI26447) with Leber Congenital Amaurosis/Severe Early Childhood Onset Retinal Dystrophy (SECORD) with heterozygous mutations in IMPDH1, showing diffuse mid-peripheral RPE atrophy with sparse pigmentation.

IMPG2 encodes a component of the retinal extracellular matrix (interphotoreceptor matrix proteoglycan 2), which allows for interaction between photoreceptor cells and between photoreceptor cells and the retinal pigment epithelium (RPE) [1, 2]. It also has calcium-binding potential, which may permit it to have a role in sequestering extracellular calcium released by photoreceptors in response to light [2]. Mutations in *IMPG2* are responsible for autosomal recessive retinitis pigmentosa (RP) with early macular involvement [2, 3].

Thus far, *IMPG2* mutations that have been described are severely pathogenic, leading to nonsense-mediated decay or to a nonfunctional gene product. The mean age of onset of symptoms for these patients is 10.5 years, with night blindness being the most common initial symptom and the next most common being decreased visual acuity [2]. Many patients also have subcapsular posterior cataracts that appear later in life. Visual acuity ranges from 20/30–20/400, and mild-to-high myopia has been reported. Visual fields become progressively constricted with time, along with a gradual decrease in central sensitivity and/or the presence of paracentral scotomas [2]. Fundus exam shows optic disc pallor,

attenuated retinal vessels, and bone spicule pigmentation at the periphery and midperiphery [2]. Macular changes range from subtle mottling of macular pigment epithelium to bull's-eye maculopathy to macular chorioretinal atrophy (Fig. 39.1a). In all 17 patients (from 10 families) observed by van Huet et al. [2], fundus autofluorescence (FAF) showed macular involvement, with profound macular hypoautofluorescence observed in later stages of the disease (indicating RPE atrophy) and with hypoautofluorescence in the midperiphery with granularity (Fig. 39.1b). However, in two of the patients observed by van Huet et al. [2], only subtle macular FAF abnormalities were observed. Spectral domain optical coherence tomography shows loss of photoreceptor inner and outer segments (ellipsoid zone) before RPE cell loss, which gives rise to severe outer retinal thinning (Fig. 39.1c). In all 17 patients observed by van Huet et al., ERG was either non-recordable (mean age of 51 years) or demonstrated a severely reduced rod-cone pattern of dysfunction [2].

A hypomorphic missense allele in *IMPG2* has been identified, and the patient carrying this mutation in a homozygous state was found to have mild maculopathy and mildly affected visual function but no diagnosis of RP [2, 3].

Fig. 39.1 Case summary: 23-year-old female with rod-cone dystrophy. (a) Wide-field color fundus photograph of the left eye showing subtle macular RPE abnormalities. (b) Fundus autofluorescence of the left eye, showing a subtle ring of macular hyperautofluorescence surrounding the fovea. (c) Spectral domain optical coherence tomography of the left eye, showing an extensive extrafoveal ellipsoid zone and outer nuclear layer loss.

IQCB1 encodes IQ-Motif Containing Protein, which is expressed in the outer segment and connecting cilia of photoreceptors and believed to be involved in ciliogenesis. Recessive mutations in *IQCB1* can either cause Senior-Loken Syndrome (SLSN), which is an oculo-renal condition characterized by nephronophthisis (medullary cystic kidney disease) and Leber congenital amaurosis (LCA), or non-syndromic LCA [1].

Patients generally have an early-onset severe LCA phenotype, with pendular nystagmus and poor fixation from birth. Patients may be highly hyperopic and often have poor visual acuity (hand motion to light perception), but in the minority with better acuity, vision is 20/70 or worse. Patients may also have keratoconus or cataracts. It is important to note that while retinal examination of a 1–2 year-old patient is typically normal, one study found prominent retinal changes at

18 months in a mutation-confirmed patient. The fundus may also reveal a “lobular” pattern of subtle alternating hypo- and hyperpigmentation around the vascular arcades or diffuse retinal pigment epithelial changes. Fundus autofluorescence may reveal patchy hyper- and hypoautofluorescence areas throughout the fundus or a hyperautofluorescent ring in the parafoveal region (Fig. 40.1a). Spectral domain optical coherence tomography is useful to demonstrate the extent of photoreceptor loss (Fig. 40.1b). ERGs typically are non-detectable early in the disease course. There is a wide variability in the onset, severity, and presence of renal disease in these patients. When patients do develop nephronophthisis, it typically occurs from the second decade of life onward. Therefore, patients with *IQCB1*-related LCA should be routinely screened for renal disease due to the significant long-term risk of renal failure [2].

Fig. 40.1 Case summary: 14-year-old Asian female with a history of Leber congenital amaurosis (CEI25377) with a homozygous mutation in *IQCB1* (courtesy of Richard Weleber). (a) Wide-field fundus autofluorescence of the left eye, showing patchy hyper- and hypoautofluo-

rescence throughout the fundus, with a hyperautofluorescent ring in the parafoveal region. (b) Spectral domain optical coherence tomography of the right eye, showing extensive loss of the ellipsoid zone and the outer nuclear layer.

KCNV2 encodes a subunit of a voltage-gated potassium channel expressed in human rod and cone photoreceptors. Autosomal recessive mutations in *KCNV2* are associated with the unique phenotype of cone dystrophy with supernormal rod response (CDSRR), also known as *KCNV2* retinopathy.

Onset is usually during infancy or early childhood, with slow but variable rates of progression, and a greater degree of cone loss over time compared to rod function. Within the first decade of life, patients typically experience reduced visual acuity, abnormal color vision (most commonly in the red-green axis), and mild photophobia with impaired adaptation to bright conditions. Nyctalopia is variable and may be experienced from childhood or develop in later stages of disease [1, 2]. Nystagmus and strabismus may also be present in young patients [3, 4]. Patients often have myopia and varying degrees of astigmatism. Central scotomas are commonly observed; in patients with rod loss, peripheral fields may also constrict over time [4–6]. Best-corrected visual acuity ranges from 20/30 to 20/400, but there is marked variability between patients. Fundus findings are variable but are generally limited to the macula and begin with an impaired foveal reflex and mild retinal pigment epithelium (RPE) changes (Figs. 41.1a, 41.2a, and 41.3a) [7]. Bull’s-eye maculopathy may also be observed; this may be more readily visualized on optical coherence tomography (OCT) and fundus autofluorescence (FAF) imaging (Figs. 41.1b and 41.3b) [1, 2]. Some patients exhibit a well-circumscribed area of macular atrophy [1]. Mild optic disc pallor may also be observed in some patients [2].

FAF imaging may reveal a perifoveal ring of increased autofluorescence (AF) (Figs. 41.1b and 41.3b) [1–3, 6, 8]. Some patients may also exhibit increased AF at the fovea, which can also be seen in some other cone/cone-rod dystrophies [6]. OCT findings range from reduced intensity of the foveal EZ without disruption and focal loss of the foveal ellipsoid zone (common finding) to significant loss of outer retinal structure at the fovea (Figs. 41.1c, 41.2b, and 41.3c) [1, 8]. Patients may also have a “hyporeflective zone” on OCT [6, 8].

Dark adaptation thresholds to red and green stimuli are elevated and may be more pronounced in patients with null mutations than in those with missense variants [1]. A unique characteristic observed with full-field electroretinography (ERG) is that the scotopic b-wave in this disorder is delayed and markedly reduced or absent at low flash intensities yet normal or “supernormal” in amplitude at the highest flash intensities [3–10]. The light-adapted and flicker ERGs exhibit reduced amplitudes and prolonged implicit times, consistent with generalized cone system dysfunction [4, 11]. While some patients do not exhibit “supernormal” rod amplitudes, all exhibit delayed implicit times and a notably greater increase in b-wave amplitude with small increases in light intensity. Multifocal ERG usually shows loss of amplitudes and prolonged implicit times that are more prominent in the central rings [1]. Adaptive optics imaging reveals foveal loss of cone photoreceptors [6].

KLHL7 encodes Kelch-like protein 7, which is part of the E3 ubiquitin ligase complex of the proteasomal pathway. Mutations in *KLHL7* cause 1–2% of autosomal dominant retinitis pigmentosa (adRP) (rod-cone dystrophy) [1–3].

Broadly, when compared with adRP caused by mutations in other genes, adRP caused by *KLHL7* mutations exhibits a later age of disease onset, with median age of diagnosis of 50 years, although some patients may exhibit more rapid deterioration of visual function [3]. Interestingly, evaluation in one patient, aged 17 years, revealed a normal fundus with no deterioration in ERG parameters [2]. Initial symptoms are typical for RP, with patients presenting with nyctalopia and decreased peripheral vision. Visual acuity is usually maintained until late in the disease course, when macular atrophy may develop [3].

Fundoscopy may demonstrate a normal fundus in younger patients but usually shows mid-peripheral bone spicules in areas of RPE atrophy, attenuated vasculature, and disc pallor (Fig. 42.1a–d). Full-field ERG reveals a rod-cone pattern of degeneration but exhibits intrafamilial variability [2, 3]. Wen et al. [3] report a 3% rate of yearly decline in the photopic flicker response. Multifocal ERG usually reveals preserved responses until late in the disease course, when there may be macular atrophy. GVF testing reveals constriction of peripheral fields, paracentral scotomata, or normal visual fields in younger patients. Fields are usually limited to 10–20° by age 65, although some patients may retain peripheral islands into their 60s [3]. OCT usually reveals retinal thinning and loss of the ellipsoid zone but with foveal preservation (Fig. 42.1e–f) [3]. CME has also been reported [2, 3].

Fig. 42.1 Case summary: 56-year-old female with late-onset rod-cone dystrophy with a mutation in *KLHL7*, with best-corrected visual acuity of 20/40 in both eyes. (a, b) Color fundus photographs of the right and left eyes, showing RPE atrophy along and outside the arcades. (c) Fundus autofluorescence image of the right eye, showing hypoautofluo-

rescent areas along and outside the arcades in areas of RPE atrophy as well as hyperautofluorescent rings surrounding the foveae in both eyes. (d, e) Spectral domain optical coherence tomography, showing significant ellipsoid zone and outer nuclear layer loss in both eyes, with sparing at the fovea. There are also mild epiretinal membranes in both eyes.

LCA5 encodes lebercilin, which is involved in microtubule transport. Mutations in *LCA5* cause 1–2% of autosomal recessive Leber congenital amaurosis [1–5].

Patients with *LCA5* mutations typically present within the first few months of life with poor pupillary reflexes, roving eye movements, oculodigital sign, high hyperopia, and pendular nystagmus. Given poor visual function and nonrecordable electroretinogram (ERG), pupillary response thresholds using direct transient pupillary light reflex measurements have been used to quantify function and were found to be elevated by over 5.5 log units in one study [6]. Bilateral keratoconus has been reported in one family [5]. Visual acuity is generally very poor and may range from 20/100–20/400 or worse (Mohamed et al. and Jacobson et al. reported LP in all patients from two families [2, 6]). Very young patients may exhibit a normal fundus, but patients eventually develop attenuated vasculature, pigment mottling, and bone spicule deposits (Figs. 43.1 and

43.2a). White dots, posterior staphyloma, macular atrophy, and early-onset cataracts have also been reported in one family; macular atrophy may progress to a coloboma-like appearance [2]. Metallic sheen of the macula [7] and optic disc drusen [1, 6] have also been reported. Hyperopia may progress with age [3]. Fundus autofluorescence may show hyperautofluorescence at the fovea (Fig. 43.2b). The full-field ERG is extinguished at an early age [3]. When recordable, it may show a rod-cone pattern of degeneration [5]. When fields are recordable, Goldmann visual field testing may show small central islands of vision [6]. Jacobson et al. reported that optical coherence tomography (OCT) reveals abnormal retinal lamination that worsens with eccentricity from the fovea; outer retinal structures may be maintained at the fovea (Fig. 43.2c). Infrared autofluorescence may show preserved RPE in younger patients in areas of maintained photoreceptor integrity (as seen on OCT) [6].

Fig. 43.1 Case summary: 22-year-old man with Leber congenital amaurosis. (a) Color fundus photograph of the right eye, showing macular atrophy and midperipheral patchy retinal pigment epithelium changes.

Fig. 43.2 Case summary: 20-year-old with Leber congenital amaurosis, onset at birth, visual acuity 1.3 logMAR (Snellen 20/400). (a) Color fundus photograph of the left eye, showing a mildly pale disc, attenuated vessels, and mid-peripheral retinal pigment epithelium mottling in the macula. (b) Fundus autofluorescence of the left eye, showing a small central residual hyperautofluorescent island. (c) Spectral domain-optical coherence tomography, showing ellipsoid zone loss outside the fovea.

LRAT encodes lecithin retinol acyltransferase, which catalyzes the earlier reactions in the retinoid visual pathway in the retinal pigment epithelium (RPE). Recessive mutations in *LRAT* cause a spectrum of disease that ranges from Leber congenital amaurosis (LCA) to forms of “juvenile” or “early-onset” retinitis pigmentosa (RP) that present slightly later in life [1–3].

Patients with recessive mutations in *LRAT* may present within the first few years of life (often less than 3 years of age) with poor visual acuity, progressive and severe night blindness, impaired dark adaptation, and photophilia; some patients may have nystagmus and abnormal color vision [2, 4]. Fundus findings include retinal vascular attenuation, disc pallor, and bilateral peripheral atrophy; retinal pigmentation or bone-spicule deposits are uncommon. Some patients may have RPE mottling at the macula that extends to the arcades. Epiretinal membranes and asteroid hyalosis have been reported as well. Fundus autofluorescence (FAF) reveals

globally reduced signal intensity, reflecting reduced lipofuscin accumulation, though there may be rare patchy increased signal intensity in the macula or around the optic disc. OCT may show a broadened foveal pit and outer retinal hyperreflective deposits, with poorly defined retinal lamination [4]. The inner segment/outer segment (IS/OS) (ellipsoid zone) line, which reflects photoreceptor integrity, may be maintained in younger patients [4]. A “saw-tooth” pattern in the nerve fiber layer was reported in three of four patients with *LRAT* mutations [4]. The visual field is significantly reduced, and the full-field electroretinogram (ERG) is non-recordable at an early age. When the ERG is recordable, it is usually only photopic responses that are detected, corresponding to a rod-cone pattern of degeneration. Goldmann Visual Field (GVF) reveals constricted visual fields in a rod-cone pattern. Further specialized testing, such as static threshold perimetry and dark-adapted spectral sensitivity testing, may reveal the extent of loss of rod and cone function [4].

MAK encodes a protein kinase involved in the regulation of photoreceptor-connecting cilium length in its longer isoform [1], which is present in the inner segments, cell bodies, and axons of rod and cone photoreceptors [1, 2]. Its shorter isoform predominates in the testes [3]. Mutations are responsible for autosomal recessive retinitis pigmentosa (RP).

The most frequently encountered mutation in *MAK* is a 353-bp insertion of an Alu repeat in exon 9 [1, 2], which has a carrier frequency of 1 in 55 in the Ashkenazi Jewish population, suggesting that it would be responsible for about 33% of RP in this group of individuals [1]. Nonsense and missense mutations in *MAK* have been identified in other populations, although at a lower frequency, with homozygous mutations present in 11 of 334 individuals screened with isolated or autosomal recessive RP [4]. Age of onset for individuals with *MAK* mutations varies from 20 to 60 years, and symptoms appear to be less severe than other types of RP. Visual acuity is often 20/50 or better in at least one eye until the 70s [1, 4]. On fundus exam, individuals display typical pigmentary changes in the midperipheral retina, vessel attenuation, and waxy pallor of the optic nerve head (Fig. 45.1a) [1]. Fundus autofluorescence may

show areas of macular hyperautofluorescence and hypoautofluorescence in areas of retinal pigment epithelium (RPE) atrophy (Fig. 45.1b). In the population homozygous for the Jewish founder mutation, Optical coherence tomography (OCT) shows decreasing foveal photoreceptor layer thickness with increasing distance from the fovea (Fig. 45.1c), and some patients display hyperthickness of the paracentral inner retina. On electroretinography (ERG) in this same population, only 4 of the 24 patients had detectable rod ERG b-waves, while 13 had a detectable cone flicker. All showed rod-cone dysfunction. On Goldmann visual field testing, visual field was seen to decrease at 11% per year for the large isopter target and 18.4% per year for the smaller target. Early loss was seen in the superior-temporal quadrant, later loss in the superior and midperipheral fields, and only central islands were present at late stages of disease. The nasal field was relatively spared [1]. In populations with other mutations in *MAK*, visual field was also observed to be significantly constricted, with half of the 8 subjects in the study by Ozgul et al. [4] demonstrating tunnel vision of 25° or less. However, two of these patients had only sectoral RP [4].

Fig. 45.1 Case summary: 34-year-old man with RP. (a) Wide-field color fundus photograph of the left eye, showing nasal RPE atrophy and bone spicule pigmentation prominent in the mid-peripheral retina. (b) Wide-field fundus autofluorescence of the left eye, showing areas of abnormal macular hyperautofluorescence and nasal areas of hypoauto-

fluorescence corresponding to RPE atrophy and pigment deposition. (c) Spectral domain optical coherence tomography of the left eye, showing essentially normal macular architecture except for temporal loss of the ellipsoid zone.

MERTK encodes the widely-expressed tyrosine-protein kinase Mer, which is a receptor tyrosine kinase involved in a signal transduction pathway that regulates numerous cellular processes. In the retina, it is expressed in the RPE and plays a role in the phagocytosis of rod outer segments. Autosomal recessive mutations in *MERTK* cause retinitis pigmentosa (rod-cone dystrophy) [1–4].

Visual symptoms include nyctalopia, progressive constriction of peripheral visual fields, and loss of visual acuity. Symptom onset occurs within the first two decades of life. Visual acuities are usually 20/50 or better before age 16, although in one family with macular atrophy, patients had light perception only vision by age 9; acuity declines progressively and is often light perception only before age 50 [1, 2, 4]. Posterior subcapsular cataracts are common. Fundus examination findings reveal arteriolar attenuation and bone-spicule pigment deposits in the mid-periphery with atrophy. Many patients have been reported to have macular abnormalities, including crystalline deposits, RPE pigment mottling, macular atrophy, and bull's eye maculopathy

(Figs. 46.1a and 46.2a). Some patients exhibit a ring of hyperautofluorescence around a hypoautofluorescent fovea (Figs. 46.1b, 46.2b, d, and 46.3a). Areas of macular atrophy are hypoautofluorescent and are sometimes surrounded by a region of hyperautofluorescence similar to that seen in geographic atrophy associated with advanced dry age-related macular degeneration [3, 5]. Optical coherence tomography (OCT) usually reveals thinning of the outer retina, debris-like material in the subneurosensory space, and disruption of the external limiting membrane/ellipsoid zone/RPE (Figs. 46.1c, 46.2c, and 46.3b) [4, 5]. Full-field electroretinography demonstrates a rod-cone pattern of degeneration within the first decade of life and tends to decline with age [1–4]. Goldmann visual field (GVF) testing may be normal in young teenagers but typically illustrates progressive peripheral constriction in a rod-cone pattern.

In one study, a homozygous loss of function of *MERTK* due to uniparental disomy was reported. The ophthalmic phenotypes described in this patient were similar those described above [6].

Fig. 46.1 Case summary: 12-year-old male with rod-cone dystrophy associated with mutations in *MERTK*. (a) Color fundus photograph of the left eye, showing macular atrophy and retinal pigment epithelium (RPE) changes. (b) Fundus autofluorescence, showing macular hypo-

autofluorescence with surrounding abnormal hyperautofluorescence. (c) Spectral domain-optical coherence tomography (SD-OCT), showing significant ellipsoid zone (EZ) loss in the macula.

Fig. 46.2 Case summary: An 11-year-old male with *MERTK* retinopathy. (a) Color fundus photograph of the right eye, showing RPE mottling and pigment clumping in the macula. (b) Fundus autofluorescence of the left eye, showing macular hyperautofluorescent foci. (c) Spectral

domain-OCT, showing EZ loss with foveal-sparing, with epiretinal membranes in both eyes and cystic changes in the right eye. (d) Fundus autofluorescence (55°) of the same patient at age 14, showing marked cystoid macular edema and macular hyperautofluorescent foci.

Fig. 46.3 Case summary: A 16-year-old patient with *MERTK*-related disease. **(a)** Fundus autofluorescence of the right and left eyes, showing central hyperautofluorescent foci in both eyes, with hypoautofluorescent spots along the superior arcades in the right eye and

superotemporal to the fovea in the left eye. 55-degree autofluorescence demonstrates hyperautofluorescent foci outside the arcades in both eyes. **(b)** Spectral domain-OCT of the right and left eyes, showing epiretinal membranes and diffuse macular EZ loss.

MYO7A encodes an unconventional myosin, which acts as an ATPase-driven motor protein to transport melanosomes and phagosomes along actin filaments in the RPE and opsin and other phototransduction proteins in photoreceptors [1]. Mutations in *MYO7A* are associated with Usher Syndrome type 1B (USH1B).

MYO7A-related Usher syndrome type 1B follows an autosomal recessive pattern of inheritance. Type 1 Usher syndrome is characterized by severe-to-profound non-progressive sensorineural hearing loss (SNHL), pre-adolescent onset retinitis pigmentosa (RP), and often vestibular areflexia [2–4]. Visual acuities are typically better than 20/60 in the first

two decades of life [2]. Visual fields in USH1B patients start with mid-peripheral loss and progress to residual small central islands, with a small temporal peripheral field in the most advanced stages of the disease. Funduscopy reveals arteriolar attenuation and RPE atrophy with bone-spicule like pigmentation (Figs. 47.1, 47.2a, and 47.3) [4–7]. Fundus autofluorescence may show a ring of hyperautofluorescence in the macula (Fig. 47.4a). Optical coherence tomography (OCT) reveals loss of outer retinal structure, sparing the fovea, and cystoid macular edema is frequently present (Figs. 47.2b and 47.4b). Full-field electroretinogram (ERG) shows severely reduced or nonrecordable parameters.

NMNAT (nicotinamide mononucleotide adenylyltransferase) is an enzyme involved in catalyzing NMN (nicotinamide mononucleotide) into NAD (nicotinamide-adenine dinucleotide). It also acts as a chaperone for neuronal maintenance and protection, particularly axonal protection [1]. The *NMNAT1* gene product protects against neuronal activity-induced degeneration in mature photoreceptors. Mutations are responsible for a severe form of Leber congenital amaurosis (LCA) [2]. The c.769G > A (p.Glu257Lys) mutation (allele frequency \approx 0.001 [3]) is the most common and is hypothesized to be a founder mutation in those of European descent [2, 4, 5].

NMNAT1 mutations likely cause <5% of LCA [5, 6]. The inheritance pattern is autosomal recessive. Patients present in the first years of life with severe and rapidly progressive macular degeneration, causing severe central atrophy with

congenital macular coloboma in the neonatal period, and with early-onset atrophy of the optic nerve. Pseudocoloboma and optic atrophy are not present at birth; they are likely due to rapid degeneration of central photoreceptors and ganglion cells due to light exposure after birth [2]. As seen in other forms of LCA, patients also demonstrate nystagmus and severe vision loss [4]. Symptoms associated with *NMNAT1* mutations tend to be earlier onset and more rapidly progressive than in other LCA patients. Homozygotes and compound heterozygotes are legally blind, with some demonstrating light perception or hand motion visual acuity [5]. Fundus exam shows macular atrophy with macular coloboma or pseudocoloboma, attenuated blood vessels, pigmentary retinal changes, and optic disc pallor (Figs. 48.1a, b) [4, 5]. ERG is typically undetectable [7].

Fig. 48.1 Nine year old girl with Leber congenital amaurosis with onset at 2 months of age and light perception visual acuity. **(a)** Color fundus photograph of the right eye, showing a pale disc, attenuated vessels,

peripheral RPE atrophy, and marked macular retinal/RPE/choroid atrophy. **(b)** Spectral domain-optical coherence tomography, showing a coloboma in the setting of extensive macular outer retinal atrophy.

NR2E3 encodes a nuclear receptor that plays a role in retinal photoreceptor differentiation [1]. Mutations in *NR2E3* cause autosomal recessive enhanced S cone syndrome (ESCS), Goldman-Favre Syndrome (GFS), clumped pigmentary retinal degeneration (CPRD), recessive retinitis pigmentosa, and dominant retinitis pigmentosa [2, 3].

Patients with autosomal recessive ESCS caused by *NR2E3* mutations present in the first decade with night blindness and reduced visual acuity [2]. Color vision is often defective, showing tritan sparing. Many patients are hyperopic, and cataracts have been observed; nystagmus is uncommon. The fundus is classically characterized by nummular pigment deposits at the level of the RPE along or outside the vascular arcades with RPE atrophy (Figs. 49.1a–c and 49.2a, d). However, the fundus may be normal in some young patients, and other patients may exhibit only mild focal hyperpigmentation or yellow-white dots rather than the classic nummular pigmentation [4]. Foveal schisis is commonly observed (Figs. 49.1e and 49.2c). Vitreous cells are common, and some patients have other vitreous opacities, such as haze and veils [4]. OCT may reveal foveal schisis, intraretinal cysts, increased retinal thickness early in disease, and lamellar disorganization with disease progression (Figs. 49.1e and 49.2c) [5]. Fundus autofluorescence may reveal hypoautofluorescence outside the arcades, patchy hyperautofluorescence inside the arcades, and spoke-like hyperautofluorescence at the fovea in the context of foveal schisis (Fig. 49.1d). The ERG is characterized by these pathognomonic findings: undetectable rod-only responses, similar waveforms in response to a bright flash under scotopic and photopic conditions, reduced flicker amplitude, and increased latency for the single flash photopic response [6]. These findings result from rod photoreceptor precursors being directed to a different fate, resulting in an increase in the concentration of S-cones. This phenomenon is also illustrated by increased amplitudes in response to shorter wavelength stimuli. Certain mutations have been shown to retain residual rod function

and therefore may represent milder disease [7, 8]. GVF may reveal constricted peripheral fields, ring scotomata or relative central scotoma (Fig. 49.2b).

NR2E3 mutations can also cause Goldmann-Favre syndrome, which is part of a clinical spectrum of disease that includes ESCS [9]. It is also characterized by childhood onset of night blindness and reduced visual acuity. Posterior subcapsular cataracts (PSC) are commonly observed. Common fundoscopic findings include progressively increasing clumped pigment deposits, peripheral or macular schisis, and liquefaction or fibrillary vitreous degeneration (Figs. 49.1 and 49.2). ERG often reveals non-recordable or severely reduced rod and cone parameters and may show enhanced S-cone function [10].

Recessive *NR2E3* mutations have also been identified in clumped pigmentary retinal degeneration (CPRD) and in RP, which may both be parts of the spectrum of ESCS. CPRD, first described by To et al., is characterized by night blindness, gradually constricting peripheral fields, and progressively increasing clumped pigment deposits in the fundus (especially in the mid-periphery) [11, 12]. Hyperopia is common in these patients. Subretinal white dots, macular holes, vessel attenuation, and atrophic scars may also be seen.

Most patients with recessive RP caused by mutations in *NR2E3* present with reduced visual acuity, hyperopia, and clumped pigmentary deposits (similar to CPRD) [13–15]. Some of these patients exhibit reduced rod parameters and supranormal dark- and light-adapted cone parameters, similar to patients with ESCS, but others have significantly reduced cone and rod parameters. Fundus features are variable, even in patients with the same mutations [13]. Findings range from flecks similar to *ABCA4*-related disease, cystoid macular edema and schisis, macular atrophy, and nummular pigmentation outside the arcades.

There is significant intra- and interfamilial phenotypic variability in disease caused by *NR2E3* mutations [13]. Escher et al. [16] reported a family with some members that had ADRP while others had ESCS [16]. There are

Fig. 49.1 Case summary: 34-year-old female diagnosed with RP at age 12 presented with photopsias in the right eye for 6–8 months and “dark spots in the inferior field” for 1–2 months; good general health otherwise; no other affected family members; visual acuity 20/40 OD and 20/30 OS. **(a)** Fundus photos OD and OS, showing RPE atrophy and pigment clumping outside the arcades. **(b)** Peripheral photos

OD, showing peripheral RPE atrophy and pigment clumping. **(c)** Peripheral photos OS, showing peripheral RPE atrophy and pigment clumping. **(d)** FAF OD and OS, showing hyperautofluorescence in the parafovea with hypoautofluorescence outside the arcades corresponding to areas of RPE atrophy and pigment clumping. **(e)** Spectral domain OCT OD and OS, showing inner retinal schisis temporal to the fovea.

Fig. 49.2 (continued)

reports of subfoveal neovascularization and cystic maculopathy associated with *NR2E3* mutations. One study reported diffuse subretinal bleeding and fibrosis, and another reported reduced visual acuity with bilateral subretinal helicoid fibrosis without other fundus features in a consanguineous family with homozygous mutations [17, 18]. In addition, this same homozygous mutation (p. R311Q) has also been reported to result in ESCS, GFS,

CPRD, and recessive RP in different patients, further emphasizing the phenotypic variability associated with mutations in this gene.

Autosomal dominant RP has also been reported to be caused by mutations in *NR2E3* [3, 19]. These patients present with night blindness and sometimes with photophobia between the first and third decades. Funduscopy may reveal pigmentary deposits in a mixed bone spicule and nummular

Fig. 49.3 Right eye fundus photograph of a 42 year old woman with subretinal fibrosis.

clumped pattern, optic nerve pallor, vessel attenuation, and peripheral atrophy. ERG usually reveals a rod-cone pattern of degeneration but may be non-recordable, especially in older patients. Unlike autosomal recessive mutations in *NR2E3*, S-cone function has not been reported to be increased in patients with autosomal dominant *NR2E3*-related RP. Fundus autofluorescence often reveals two rings of hyperfluorescence - a ring in the macula (which constricts with age) and another ring along the arcades, which can expand with time [20]. Escher et al. [20] report that the IS-OS line (ellipsoid zone), which reflects photoreceptor integrity, is lost within the confines of these two hyperfluorescent rings [20]. Nummular hypoautofluorescent areas have been reported around the arcades in patients without funduscopic evidence of pigmentation. GVF reveals constricted fields and peripheral loss with mid-peripheral scotomata. One study has shown that pupil responses to rod-specific stimuli may be useful to detect progression of disease [21].

NRL encodes the transcription factor neural retina leucine zipper, which is involved in regulating the expression of rod-specific genes. It is essential for rod photoreceptor differentiation during retinal development. Mutations in *NRL* are associated with retinitis pigmentosa and clumped pigmentary retinal degeneration [1–3].

NRL-related retinitis pigmentosa most commonly follows an autosomal dominant pattern of inheritance, with autosomal recessive disease less commonly described. Patients experience night blindness initially, with an onset between early childhood and the second decade of life, with significant peripheral visual field constriction by their third to fourth decades of life [1–3]. Fundoscopy reveals typical

signs of RP (Figs. 50.1a and 50.2a). Peripapillary atrophy may also be observed in both younger and older patients [1]. Fundus autofluorescence imaging may identify a perifoveal ring of increased autofluorescence at an early stage in young patients (Figs. 50.1b, c and 50.2b) [1]. Spectral domain-optical coherence tomography (SD-OCT) is useful to demonstrate the extent of photoreceptor loss in the macula and may show foveal-sparing early in the disease course (Figs. 50.1d and 50.2c). Full-field electroretinograms (ERG) may reveal non-recordable scotopic responses, but well-preserved photopic responses in younger patients. Older patients may have both non-recordable scotopic and photopic ERGs [1–3].

Fig. 50.1 Case Summary: Male patient with a mutation in *NRL*. (a) Color fundus photos of the right and left eyes at age 12, showing an unremarkable macular appearance with peripheral pigment deposits visible outside the arcades (OD > OS). (b) Macular fundus autofluorescence of the right and left eyes at age 13, showing a macular ring of hyperautofluorescence. (c) Wide-field fundus autofluorescence of the

right and left eyes at age 13, showing the macular rings of hyperautofluorescence as well as hypoautofluorescence outside the arcades, corresponding to areas of atrophy and pigment deposition. (d) Spectral domain-optical coherence tomography (SD-OCT) of the macula in the right and left eyes, showing outer nuclear layer and ellipsoid zone (EZ) loss outside the foveal center, with a faint epiretinal membrane.

Fig. 50.1 (continued)

Fig. 50.2 Case Summary: (a) Color fundus photo left eye at age 63 (media opacity over optic nerve suspected to be secondary to cataract), showing extensive macular atrophy with pigment deposition as well as peripheral chorioretinal atrophy with dense pigmentation outside the arcades. There appears to be a residual area of parafoveal retinal pigment epithelium (RPE) surrounding the central atrophy. (b) Fundus autofluorescence of the right eye at age 70, showing macular and

peripheral hypoautofluorescence corresponding to areas of atrophy and pigmentation. The residual RPE in the parafovea exhibits abnormal hyperautofluorescence. (c) Spectral domain-OCT at age 70, showing extensive loss of the EZ in the macula with a residual (abnormal-appearing) scattered RPE band corresponding to hyperautofluorescent areas in the macula shown in Fig. 50.2b.

Mutations in *NYX*, which encodes nyctalopin, causes 45% of X-linked congenital stationary night blindness [1]. Males with CSNB caused by mutations in *NYX* often present in the first decade with reduced visual acuity (20/30–20/200), night blindness in up to 97.2% of patients, myopia (average refraction −9.19 diopters in one study, more myopic than *CACNA1F* patients), usually normal color vision, nystagmus (40%) and strabismus (29.4%) [2, 3]. The fundus usually appears normal on fundoscopy (Figs. 51.1a and 51.2a), fundus autofluorescence (Figs. 51.1b and 51.2b), and optical coherence tomography (Fig. 51.2c), but patients with high myopia may exhibit myopic degeneration. Full-field ERG reveals severely decreased responses to dim scotopic flashes; a characteristic negative ERG on maximum scotopic stimu-

lation testing, in which the b-wave to a-wave ratio is less than 1; and squaring of the photopic a-wave due to loss of the second oscillatory potential. These changes are thought to reflect an ON-pathway [2]. At high flicker frequencies, the photopic flicker amplitudes were attenuated in one study [4]. One study has shown that patients with *NYX* mutations exhibit less phenotypic variability with respect to visual acuity, refractive error, and scotopic b/a wave ratio than patients with mutations in *CACNA1F* [2, 3]. Female carriers of *NYX* mutations tend to be asymptomatic and exhibit normal funduscopy and electrophysiologic examinations.

Studies by Zhang et al. [5] and Yip et al. [6] have reported high myopia without features of CSNB in some patients with mutations in *NYX*.

Fig. 51.1 Case Summary: 6-year-old male with CSNB with a mutation in *NYX*. (a) Wide-field color fundus photograph of the right eye, showing an essentially unremarkable right fundus. (b) Wide-field fundus autofluorescence, showing a normal pattern of autofluorescence.

Fig. 51.2 Case Summary: 11-year-old male (CEI28443) with complete CSNB with a mutation in *NYX*. (a) Montage color fundus photograph of the right eye, showing an essentially unremarkable fundus. (b) Wide-field fundus autofluorescence, showing a normal pattern of autofluorescence except for patchy hyperautofluorescence around the optic nerve. (c) Spectral domain optical coherence tomography, showing good preservation of the retinal layers.

OAT is a nuclear gene that encodes a mitochondrial enzyme that acts as an ornithine aminotransferase. Mutations in *OAT* are associated with gyrate atrophy of the choroid and retina, which follows an autosomal recessive pattern of inheritance [1–5]. Patients typically present with nyctalopia and/or loss of peripheral vision in their second decade of life, though some patients may present with progressive myopia or poor central vision. Patients may also manifest early cataracts (typically in the second decade of life) [2, 3, 6, 7]. Visual acuities vary within age groups, ranging from 20/40 to light perception, and decline with age [1].

Patients with gyrate atrophy typically have higher plasma ornithine levels (usually 10–20 times higher than normal) [8, 9]. Fundoscopy reveals scalloped retinal pigment epithelium (RPE) and circular chorioretinal atrophic areas in the periphery (Fig. 52.1a). Optic disc atrophy, macular changes, and arteriolar attenuation may also be observed. The macula and central vision are typically preserved until the fourth and fifth decades of life. Fundus autofluorescence (FAF) imaging reveals characteristic areas of hypoautofluorescence corresponding to areas of atrophy; a hyperautofluorescent region may surround these areas. Some patients may exhibit a hyperautofluorescent ring in an otherwise normal parafovea, while others may reveal speckled hyperautofluorescence in areas of the macula with normal retinal cross-sectional architecture [5, 10]. Spectral-domain optical coherence tomography (SD-OCT) may reveal cystoid spaces in the inner nuclear layer and exhibit hyper-reflective deposits in the ganglion

cell layer (Fig. 52.1b) [2, 5]. Areas of preserved ellipsoid zone (EZ) have been noted to correspond to areas of normal or hyperautofluorescent areas on FAF imaging, similar to other retinal dystrophies [2]. As would be expected, the areas corresponding to hypoautofluorescent atrophy on FAF exhibit thinning and loss of outer retinal layers [2, 5]. Thickening of the foveola may be observed in younger patients, while older patients may exhibit outer retinal tubulation, which is characterized by tubular hyporeflective spaces surrounded by hyperreflective borders [2, 3]. There are varying degrees of retinal atrophy in areas of peripheral chorioretinal degeneration, or, at a minimum, interruption of the ellipsoid zone [2]. Cystoid macular edema has also been reported in some patients [2, 3]. Full-field electroretinography (ERG) recordings are variable but typically show both abnormal cone and rod responses, which can sometimes be completely extinguished [1, 10].

Microperimetry reveals that areas with maintained retinal architecture and normal autofluorescence may exhibit reduced sensitivity, while areas corresponding to atrophy show no response to bright stimuli [2]. Patients with gyrate atrophy may be treated with a low arginine protein diet to slow progression of disease [10–13]. There is a subset of patients that may respond to pyridoxine (vitamin B6), which is a cofactor for the *OAT* enzyme. These patients exhibit reduced plasma ornithine levels and slower progression of disease with daily pyridoxine supplementation [14, 15].

Fig. 52.1 Case Summary: 30-year-old woman with gyrate atrophy, diagnosed based on elevated ornithine levels, OCT performed at age 34. (a) Wide-field color fundus photograph of the left eye, showing scalloped chorioretinal atrophy with pigment deposition and retinal vessel

attenuation. (b) Spectral domain optical coherence tomography of the left eye, showing intraretinal cystic changes with overall maintenance of the ellipsoid zone in the macula.

OPN1LW and *OPN1MW* lie side by side on the X-chromosome and encode the long-wavelength (red) and middle-wavelength (green) cone opsins, respectively. Mutations in these genes cause a wide array of X-linked conditions ranging from red-green dyschromatopsia, blue cone monochromacy (BCM), cone/cone-rod dystrophy, and high myopia.

BCM is caused by mutations involving both *OPN1LW* and *OPN1MW* (sometimes from unequal crossing over that results in a single mutated hybrid gene) or in the locus control region lying upstream of these genes [1–5]. Patients typically present within the first decade with photophobia, pendular nystagmus, and poor visual acuity (typically between 20/60 and 20/400) [3, 6, 7]. Patients may exhibit central scotomas and eccentric fixation. Patients also typically exhibit severe color vision defects, observed with various types of testing (i.e. Mollon-Riffen [RF] Minimal and Hardy-Rand-Rittler [HRR] pseudoisochromatic Plates), showing poor discrimination along the protan and deutan axes but maintained discrimination of tritan axes [3]. Myopia is very common in patients with BCM [3, 8]. Fundus examinations in younger patients are often unremarkable or show mild macular retinal pigment epithelium (RPE) changes, while older patients may exhibit macular atrophy, which may be better visualized with fundus autofluorescence (FAF) imaging (Figs. 53.1 and 53.2a) [3, 9, 10]. Spectral domain optical coherence tomography may reveal reduced foveal thicknesses and varied disruption of the ellipsoid band around the foveal center (Fig. 53.2b) [10–12]. Patients crossing-over mutations may exhibit a wider area of ellipsoid band loss than those with missense mutations [12]. Adaptive optics may be useful in further evaluating the degree of foveal cone photoreceptor loss in areas of ellipsoid disruption [10, 12]. Electroretinograms (ERG) usually show

normal rod responses but severely reduced photopic parameters. ERG testing using monochromatic stimuli may reveal absent green and red responses and normal responses to blue light [11].

Certain mutations have also been reported to cause X-linked cone/cone-rod dystrophy [2, 5, 13–16]. These patients also tend to present with poor visual acuity within the first decade; myopia is common (not high myopia), while nystagmus is uncommon [13]. One study reported that these patients may present in the second or third decades and retain better visual acuity [2] than those with BCM. Similar to those BCM, most of these patients retain discrimination along the tritan axis, with abnormalities in the protan and deutan axes [13]. Fundus findings range from mild RPE pigment changes at an early age to macular atrophy in older patients. FAF may be normal in young patients or exhibit a parafoveal ring of hyperautofluorescence; there is hypoautofluorescence in areas of atrophy [13]. ERG usually reveals abnormal photopic parameters with normal scotopic parameters [2, 5, 13]. Some patients may exhibit a cone-rod dystrophy phenotype with progressive deterioration in both photopic and scotopic ERG parameters [2].

Some patients exhibit a phenotype described as X-linked myopia with cone dysfunction [14]. These patients exhibit moderate-to-high myopia, reduced visual acuity, and protanopia. The fundoscopic exam is usually normal except for myopic changes in some patients. The full-field ERG reveals abnormal cone function that does not deteriorate with time [14].

Female carriers are typically clinically unaffected, but some may exhibit evidence of cone dysfunction with ERG testing [13]. There has been a report of BCM in a female resulting from an abnormal X-inactivation pattern [11].

Fig. 53.1 Case Summary: 3-year-old male with BCM. Color fundus photograph of the right eye, showing a normal fundus.

Fig. 53.2 Case summary: 49-year-old man with BCM. (a) Color fundus photograph of the right eye, showing loss of the foveal reflex and foveal atrophy. (b) Spectral domain optical coherence tomography, showing foveal ellipsoid zone loss with cavitation.

PDE6A encodes the alpha-subunit of the cGMP phosphodiesterase in rod photoreceptor cells that transmits visual signals during phototransduction. Mutations in *PDE6A* cause 2–5% of autosomal recessive retinitis pigmentosa (rod-cone dystrophy) [1–5]. Increased intracellular calcium and apoptosis resulting from reduced cGMP phosphodiesterase activity is thought to be a possible mechanism for rod photoreceptor cell loss [6].

These patients typically present with nyctalopia and peripheral field loss in early childhood. Visual acuity is usually maintained until later in the disease course. Fundus findings demonstrate typical signs of RP, including optic disc

pallor, retinal vascular attenuation, and classic bone-spicule deposits in the mid-peripheral retina, which may be extensive (Fig. 54.1a) [4]. The full-field electroretinogram reveals a rod-cone pattern of degeneration; scotopic responses are often non-recordable. Tsang et al. [4] reported that vitreomacular traction is seen in some patients, and this may be best visualized on optical coherence tomography (Fig. 54.1c); fundus autofluorescence may reveal a hyperautofluorescent ring in the macula (Fig. 54.1b), in which the microperimetric thresholds are elevated. Bilateral cystoid macular edema has also been reported [4].

Fig. 54.1 Case Summary: 15-year-old female with retinitis pigmentosa (simplex) (CEI26433) with mutations in *PDE6A*. (a) Montage color fundus photograph of the left eye, showing bone spicule pigmentation and RPE atrophy in the mid-peripheral retina. (b) Wide-field fundus autofluorescence of the left eye, showing hypoautofluorescence associated with bone spicule pigmentation, with surrounding foci of

hyperautofluorescence. There is also a hyperautofluorescent ring in the macula. (c) Spectral domain optical coherence tomography of the left eye, showing extrafoveal loss of the ellipsoid zone and outer nuclear layer, cystoid changes at the fovea, as well as a faint temporal epiretinal membrane.

PDE6B encodes the beta-subunit of the cGMP phosphodiesterase in rod photoreceptor cells that plays a key role during phototransduction. Mutations in *PDE6B* cause 2–5% of autosomal recessive retinitis pigmentosa (rod-cone dystrophy) [1] and rarely autosomal dominant congenital stationary night blindness (CSNB) [2].

Patients with recessive mutations in *PDE6B* report nyctalopia and peripheral field loss starting in early childhood [1, 3, 4]. Visual acuity is generally maintained (better than 20/40) until later in the disease course. Fundus findings are typical for retinitis pigmentosa, including optic disc pallor, retinal vascular attenuation, and bone-spicule deposits in the mid-peripheral retina, which progresses to peripheral atrophy that may ultimately involve the macula (Fig. 55.1); some patients may exhibit cystoid macular edema. The full-field electroretinogram (ERG) reveals a rod-cone pattern of degeneration; scotopic responses are often non-recordable [4]. Dark adaptation thresholds are elevated, and Goldmann visual field testing reveals constriction starting in the mid-peripheral fields followed by extension to the periphery and

finally constriction centrally. Spectral domain-optical coherence tomography may demonstrate outer retinal atrophy with ellipsoid zone loss, faint epiretinal membrane, and inner retinal cystic changes (Fig. 55.2a, b). Fundus autofluorescence reveals areas of hypoautofluorescence corresponding to areas of retinal pigment epithelium atrophy; some patients may exhibit a ring of hyperautofluorescence surrounding the fovea (Fig. 55.2c, d) [4]. Microperimetry shows reduced sensitivities in areas of hypoautofluorescence [4].

Certain mutations in *PDE6B* can cause dominant CSNB [2, 5]. These patients typically experience stable night blindness but maintain good central visual acuity and color vision. Funduscopy usually reveals a normal fundus, and testing reveals elevated dark adaptation thresholds, reduced to absent dark-adapted a- and b-waves, and normal photopic responses. A negative ERG, in which the b-wave to a-wave ratio is less than 1 for the scotopic b-wave under dark-adapted maximum stimulus conditions, may be observed in patients with dominant CSNB associated with mutations in *PDE6B* [5].

Fig. 55.1 Color fundus photograph of the right eye, showing mid-peripheral bone-spicule pigmentation and peripheral retinal atrophy. Case Summary: Twenty-eight year old woman with rod-cone dystrophy.

Fig. 55.2 Case Summary: 33-year-old female with cystoid macular edema. **(a)** Spectral domain-optical coherence tomography of the right eye, showing outer retinal atrophy with ellipsoid zone (EZ) loss outside the fovea, with a faint epiretinal membrane and inner retinal cystic changes. **(b)** Spectral domain-OCT of the left eye, showing EZ loss involving the fovea, with a trace ERM and inner retinal cystic changes. **(c)** Fundus autofluorescence, showing a ring of hyperautofluorescence surrounding the fovea and patchy hypoautofluorescence outside the arcades in the right eye. **(d)** Fundus autofluorescence, showing macular hyperautofluorescence and patchy hypoautofluorescence outside the arcades in the left eye.

PDE6C encodes cone cGMP-specific 3',5'-cyclic phosphodiesterase subunit alpha (cGMP phosphodiesterase 6C), which is an enzyme expressed in cone photoreceptors. Autosomal recessive mutations in *PDE6C* cause cone-specific disorders ranging from achromatopsia to cone dystrophy [1, 2].

Patients can present within the first decade with poor visual acuity, photophobia, abnormal color vision, and nystagmus; most tend to be myopic. Fundoscopy may be unremarkable or reveal mild macular pigment changes with an absent foveal reflex in the context of a normal peripheral retina; some patients may exhibit atrophy at the macula (Fig. 56.1a) [1, 2]. The electroretinogram (ERG) is notable for abnormal cone function with normal rod function, although reduced rod parameters have been reported in some patients [1–4]. Cone function worsens with age in

many patients until responses are extinguished, but some patients may exhibit a non-recordable cone ERG within the first decade of life. Goldmann visual field testing and microperimetry reveal central scotomas [1, 3]. Fundus autofluorescence may show abnormal foveal autofluorescence, ranging from hyperautofluorescence to hypoautofluorescence in cases with foveal atrophy (Fig. 56.1b). Spectral domain optical coherence tomography typically reveals a loss of the photoreceptor layer at the fovea that appears as a cavitation (or empty optical cavity) at the foveola with loss of the ellipsoid zone (Fig. 56.1c) [2, 3, 5]. While mutations in *PDE6C* cause a spectrum of disease from progressive cone dystrophy to achromatopsia, the final phenotype may be determined by the type and nature of inherited disease-causing mutations and the degree to which enzyme activity is affected [5].

Fig. 56.1 Case summary: 10-year-old girl with achromatopsia. (a) Color fundus photograph of the right eye, showing an abnormal foveal reflex at age 10 years. (b) Fundus autofluorescence of the right eye, showing abnormal areas of hyperautofluorescence at and surrounding

the fovea at age 12 years. (c) Spectral-domain optical coherence tomography, showing outer retinal foveal atrophy with ellipsoid zone loss and cavitation in the context of a broadened foveal pit at age 10.

PDE6G encodes the gamma-subunit of the cGMP phosphodiesterase in rod photoreceptor cells that plays a key role during phototransduction. Mutations in *PDE6G* are a rare cause of autosomal recessive retinitis pigmentosa (RP; rod-cone dystrophy) and autosomal dominant congenital stationary night blindness [1, 2]. Due to the rarity of mutations in this gene, limited information is available on the phenotype. Compared to other forms of RP, it exhibits an earlier onset of photoreceptor dysfunction on electroretinography (ERG); however, best corrected visual acuity was relatively good (as high as 20/40 at age 10–16). Patients present with the typical features of RP, including night blindness, reduced peripheral vision, and preserved central visual acuity. Funduscopy findings demonstrate retinal pigment epithelium (RPE) atrophy and bone-spicule pigment deposits starting in the mid-periphery and spreading to the periphery,

retinal vascular attenuation, and optic disc pallor. Macular atrophy and cystoid macular edema may also develop in some patients. Full-field ERG is usually non-recordable at an early age (as early as 4 years). Visual field testing usually reveals a central island of remaining vision ($<5\text{--}10^\circ$) from 10–16 years of age. [1].

PHYH (also called PAHX) encodes the peroxisomal protein phytanoyl-CoA hydroxylase, which is involved in the peroxisomal α -oxidation of phytanic acid. Mutations in *PHYH* cause adult Refsum disease, which is an autosomal-recessive peroxisomal disorder resulting from serum and tissue accumulation of phytanic acid. The disease has numerous features, including retinitis pigmentosa (RP) as well as peripheral polyneuropathy, anosmia, hearing loss, cardiomyopathy, cerebellar ataxia, and elevated protein levels in the cerebrospinal fluid [1, 2]. It is as yet unclear how elevated levels of phytanic acid result in disease.

All cases of adult Refsum disease exhibit retinitis pigmentosa, and most patients report ophthalmic symptoms long before other systemic issues [3]. There is typically an onset of night blindness and visual field constriction from early childhood to the second decade of life [2, 4, 5]. Visual acuities may be normal early in the disease course to very severely affected (hand movement vision) in older patients [2]. Concentric narrowing of the visual field is also common, as with other types of rod-cone dystrophy. However, progressive visual field and acuity deterioration occur over several decades after the initial onset of night blindness [2, 4]. Some patients may exhibit earlier macular atrophy, resulting in loss of visual acuity at a younger age [6]. Electroretinography (ERG) usually reveals significantly reduced or non-recordable rod and cone responses, although it is reasonable

to expect a rod-cone pattern of degeneration in patients [1]. Dietary restriction of phytanic acid levels (to less than 10 mg/day) has been shown to successfully improve ichthyosis and neurologic symptoms such as ataxia and peripheral neuropathy, but it is unknown whether this affects the progression of retinal disease [4–7].

PRCD encodes progressive rod-cone degeneration protein, whose function is poorly defined, but which is known to be a membrane protein expressed in photoreceptors [1]. Autosomal recessive mutations in *PRCD* cause retinitis pigmentosa (rod-cone dystrophy) [2, 3]. A founder mutation has been identified in the Muslim Arab population in Israel [3]. Symptoms include nyctalopia and reduced visual acuity within the first decade, with most patients exhibiting very poor visual acuity by the second decade. Myopia and posterior subcapsular cataracts are common findings [3, 4]. Fundus findings include

classic RP features, such as bone-spicule pigment deposits, optic nerve pallor, and arteriolar attenuation (Fig. 59.1a, b). Many patients also exhibit abnormal findings at the macula, such as macular puckering, central atrophy, or a bull's eye maculopathy [2–4]. The full-field ERG has been reported to be non-recordable in all published patients, including a child only 6 years of age [2–4]. Goldmann visual field testing tends to reveal peripheral field loss [2]. Spectral domain OCT reveals reduced foveal thickness, with shortened outer segments and loss of the ONL and RPE [4].

Fig. 59.1 Case summary: 45-year-old woman with pericentral retinitis pigmentosa. **(a)** Color fundus photograph of the right eye, showing pericentral pigment deposits and retinal pigment epithelium (RPE) atrophy along the inferior arcades with an otherwise unremarkable

fundus. **(b)** Fundus autofluorescence, showing hypoautofluorescence along the inferior arcades in areas of RPE atrophy with surrounding areas of hyperautofluorescence and with hyperautofluorescence along the arcades.

PROM1 encodes prominin-1, a membrane protein involved in disk morphogenesis. Mutations in *PROM1* cause autosomal dominant macular dystrophy, autosomal recessive or dominant retinitis pigmentosa (RP), or recessive cone-rod dystrophy [1–3].

Patients with macular dystrophy may present in their teens to thirties and with reduced visual acuity, photophobia, and abnormal color vision [4]. Fundus findings are characterized by bilateral macular degeneration and may include retinal pigment epithelium (RPE) changes, bull's-eye maculopathy with atrophy, or flecks (Fig. 60.1a). Fluorescein angiography usually shows hyperfluorescent macular lesions with window defects; a dark choroid has been reported in one patient but is not necessarily pathognomonic for this mutation. FAF may reveal a hyperautofluorescent perifoveal ring (Fig. 60.1b). In cases of isolated macular involvement, the full-field electroretinogram (ERG) is normal, while rod-cone or cone-rod pattern dysfunction suggests more widespread retinal involvement. Goldmann visual field (GVF) usually shows central scotomata. Optical coherence tomography (OCT) may reveal macular atrophy with retinal thinning such as a loss of the ellipsoid zone, reflecting lack of photoreceptor integrity (Fig. 60.1c); retinal tissue in the more peripheral macula may be less affected [4].

PROM1 mutations have also been shown to cause dominant RP. The initial symptom is usually reduced central vision, with night blindness becoming more noticeable with time. Age of onset may be variable, between the teens to the 50s. Unlike many other forms of RP, funduscopy commonly

reveals a bull's eye maculopathy, with variable other features of RP, including attenuated vessels, optic disc pallor, peripheral pigment, and macular atrophy. Fluorescein angiography has never been noted to exhibit a dark choroid. ERG reveals rod-cone dysfunction. OCT may reveal reduced retinal thickness, macular atrophy, or loss of photoreceptor outer segments.

Recessive RP may also be caused by *PROM1* mutations [5]. The presenting symptoms are usually night blindness and reduced acuity, which begin in early childhood. Visual acuity reduces rapidly to significantly worse than 20/200 before age 20. Nystagmus may be observed, but photophobia and keratoconus are uncommon. Fundus findings include disc pallor, progressive macular atrophy beginning with pigment clumping (often exhibiting a bull's-eye lesion), vascular attenuation, and bone-spicule pigment deposits in the mid-periphery. ERG reveals rod-cone dysfunction and is often non-recordable by the third decade. Polydactyly has been reported in one patient [5].

Recessive cone-rod dystrophy has also been reported to be caused by mutations in *PROM1* [2]. Patients present in early childhood with reduced visual acuity (may progress to counting fingers before age 20), photosensitivity, and color vision defects; night vision is affected later in life. High myopia and nystagmus are commonly observed. Fundus findings are usually limited to the macula, including bull's-eye maculopathy, with rare deposits in the periphery (Fig. 60.2). ERG is characterized by cone dysfunction with progressively deteriorating rod function over time.

Fig. 60.1 Case summary: 25-year-old woman with dominant macular dystrophy. (a) Color fundus photograph of the right eye, showing faint RPE abnormalities in the macula. (b) Fundus autofluorescence of the right eye, showing a ring of hyperautofluorescence surround-

ing the fovea. (c) Spectral domain optical coherence tomography, showing a broadened foveal pit and focal disruption of the ellipsoid zone surrounding the foveola, with an anatomically intact underlying RPE.

Fig. 60.2 Color fundus photograph of the right eye from a 51-year-old woman with cone-rod dystrophy, showing macular atrophy and retinal pigment epithelium abnormality.

PRPF3 encodes U4/U6 small nuclear ribonucleoprotein Prp3, a nuclear protein that plays a role in mRNA splicing. It is highly expressed in the retina, among many other tissues; mutations affect its interaction with the U4/U6 snRNP complex of the spliceosome [1]. Mutations in *PRPF3* cause about one percent of autosomal dominant retinitis pigmentosa (rod-cone dystrophy) [2–6]. It is not well understood how mutations in the components of the spliceosome result in a phenotype that affects only the retina [7].

Patients usually present with night blindness in childhood (first and second decades), then progressively lose peripheral fields into their thirties and forties, and usually exhibit a non-recordable electroretinogram (ERG) by the fourth decade [8–10]. Some studies, however, have reported a later onset of night blindness, as late as age 40 [4, 6]. Patients with an earlier onset of nyctalopia (within the first decade) tend to lose visual acuity more rapidly than those who experience nyctalopia in the second and third decades [6]. Most patients are myopic; nystagmus and color vision abnormalities are uncommon. Some patients develop photophobia later in the disease course [10].

Fundus findings feature classic features of rod-cone dystrophy, such as retinal vascular attenuation, optic disc pallor, retinal pigment epithelium (RPE) mottling, and bone spicule pigment deposits in the mid-periphery and peripheral retina that progresses to atrophy later in the disease course. Younger patients may exhibit a normal fundus [6]. FAF reveals hypoautofluorescence in the peripheral and mid-peripheral retina due to atrophy; some patients may exhibit granular hyperautofluorescence at the macula [8]. A hyperautofluorescent ring in the macula is common, the inner ring of which may correlate with the extent of the remaining visual field detected with the I-4e or I-3e isopters [6]. This ring may be present early in the disease course in the context of a relatively normal fundus, before any symptoms manifest. The full-field ERG is often non-recordable by the fourth decade of life, and Goldmann Visual Field (GVF)

reveals visual field constriction in a rod-cone pattern. When the full-field ERG is recordable (usually earlier in life), it exhibits a rod-cone pattern of degeneration. Dark-adaptation thresholds are elevated, as would be expected for a rod-cone dystrophy. Cystoid macular edema (CME) is uncommonly observed with mutations in *PRPF3*. Phenotypic variability, even in patients within the same family, is common, and there may be differences in visual acuity, field size, and ERG findings in patients harboring the same mutations [6].

PRPF31 encodes U4/U6 small nuclear ribonucleoprotein Prp31, which is involved in mRNA splicing. Mutations in *PRPF31* cause 8–9% of autosomal dominant retinitis pigmentosa (adRP) (rod-cone dystrophy) [1–4].

Patients with adRP caused by *PRPF31* mutations present in the first-to-third decades with nyctalopia and reduced peripheral fields but generally maintain visual acuity until late in the disease course. *PRPF31* has incomplete penetrance, as many patients carrying the disease allele do not manifest signs of disease [3–6]. There is also a great deal of variable expressivity in *PRPF31*-related disease: even patients who carry the same mutations may exhibit variable phenotypes and disease severity [2]. There is evidence that this may be caused by haploinsufficiency (reduced levels of wild-type Prp31) and has led to a model of pathogenesis in

which higher levels of normal protein are protective against disease [7, 8]. Co-occurrence of disease-causing alleles of *PRPF31* and *RHO* in a family has been reported [9].

Fundus findings are typical for RP, including peripheral bone spicule deposits and pigment mottling, optic disc pallor, and attenuated retinal vessels. As with other forms of RP, patients often develop CME and posterior sub-capsular cataracts [2, 10, 11]. OCT may reveal normal retinal lamination or exhibit CME, ERMs, or foveal thinning. FAF may reveal hypoautofluorescence outside the arcades with patchy loss of signal in the macula; there may be a perifoveal ring of hyperautofluorescence, or, rarely, hyperfluorescence at the fovea. Full-field ERG and GVF reveal a rod-cone pattern of degeneration, while multifocal ERG shows preservation of responses at the central hexagons (Figs. 62.1 and 62.2).

Fig. 62.1 Color fundus photograph from a 22-year-old man, showing attenuated retinal vasculature and midperipheral bone spicule pigment deposits.

Fig. 62.2 Color fundus photograph from the 44-year-old mother of the patient in Fig. 62.1, showing attenuated retinal vasculature and more extensive midperipheral bone spicule pigment deposits.

PRPF8 encodes pre-mRNA-processing-splicing factor 8, which interacts with the 5' and 3' ends of pre-mRNA molecules and plays a role in the assembly of spliceosome components onto pre-mRNA molecules. Mutations in *PRPF8* cause about 2–3% of autosomal dominant retinitis pigmentosa (rod-cone dystrophy) [1–10].

Patients present within the first-to-second decades of life with nyctalopia, usually followed by peripheral field loss. However, there is often significant phenotypic variability, even in family members carrying the same mutation [3–5]. For example, patients with the p.H2309P mutation were shown to exhibit an earlier age of onset (age of 6.6 years) than patients with the p.H2309R (10.7 years) and p.R2310K (22 years) mutations [3]. Visual acuity may be maintained until later in the disease course (e.g., in a family described in Walia et al, some members of the family retained visual better than 20/30 into their 40s while a few members had acuities as poor as 20/400 in their 20s [5]), though some patients may experience reductions in visual acuity as early as the second decade [4, 7]. Some mutations (p.R2310K) may exhibit a milder phenotype, with patients presenting as late as their forties and exhibiting better visual acuity over time [3].

As is typical for RP, patients may develop early-onset posterior subcapsular cataracts (Townes et al. reported 17 of 75 patients with cataracts [3], while Maubaret et al. [4] reported bilateral PCS cataracts in nearly half of their

patients). Fundus findings usually feature diffuse bone-spicule pigment deposits and retinal vessel attenuation and may also show optic disc pallor with or without optic nerve drusen (Fig. 63.1a) [3, 5]. Like other forms of RP, cystoid macular edema (CME) is common (11 of 17 patients per Towns et al. [3]). Some patients may exhibit macular pigment clumping and RPE atrophy [3, 4]. FAF reveals areas of hypoautofluorescent RPE atrophy, usually beyond the arcades, while some patients may exhibit a hyperautofluorescent perifoveal ring in the macula (Fig. 63.1b) [4, 6]. Full-field ERG is often non-recordable; when detectable, it exhibits a rod-cone pattern of degeneration [6]. Dark adaptation thresholds are elevated. GVF testing exhibits a rod-cone pattern of field loss that ultimately leaves behind a central island of vision. OCT may reveal CME, thinning, and atrophy at the macula (Fig. 63.1c), or loss of the outer retinal layers at the fovea; the outer retinal layers and architecture are usually maintained within the confines of the macular hyperautofluorescent ring on FAF imaging [3, 4]. There is often significant phenotypic variability, even in family members carrying the same mutation [3–5]. Maubaret et al. [4] reported one patient who developed a monocular Coats-like retinal telangiectasia that caused vitreous hemorrhage in his mid-thirties; they also reported one mutation-carrying patient who reported only mild symptoms and did not manifest any clinical signs of disease.

Fig. 63.1 Case summary: 10-year-old boy with retinitis pigmentosa (rod-cone dystrophy). (a) Color fundus photograph of the left eye, showing peripheral RPE atrophy with bone spicule pigment deposits and retinal vascular attenuation. (b) Fundus autofluorescence, showing a ring of hyperautofluorescence in the parafovea with midperipheral

hypoautofluorescence corresponding to RPE loss and bone-spicule deposits. (c) Spectral domain optical coherence tomography, showing extensive loss of the ellipsoid zone and outer nuclear layer outside the central fovea, with a mild epiretinal membrane and with mild cystoid macular edema visible in the inner nuclear layer.

PRPH2 encodes a membrane protein involved in photoreceptor disc morphogenesis. There is significant inter- and intrafamilial phenotypic variability with *PRPH2* mutations dystrophy [1–4]. For example, mutations in this gene have been associated with dominant retinitis pigmentosa (including retinitis punctata albescens), pattern macular dystrophy, central areolar choroidal dystrophy (CACD), or cone-rod dystrophy [5–7].

Seven-and-a-half percent of dominant RP may be caused by *PRPH2* mutations, and there is significant phenotypic variability [8–11]. Patients present with abnormal night vision and progressively constricting peripheral vision in the third to fifth decades, though some mutations may present in the first to third decades [12]. Visual acuity is usually maintained until the fifth decade. The fundus typically resembles classical RP and features bone spicule pigment deposits, peripheral atrophy, disc pallor, and vascular attenuation. ERG and GVF reveal a rod-cone pattern of degeneration. Dark adaptation thresholds are elevated, and color vision is usually normal. Some studies have reported patients with dominant RP who exhibit a maculopathy, which may range from a bull’s-eye lesion to atrophy [4, 13–15]. This subset of patients may exhibit extinguished electroretinogram (ERG) parameters as early as the second decade (Fig. 64.1).

PRPH2 mutations have also been associated with a phenotype resembling retinitis punctata albescens (RPA), which is characterized by distinctive white round deposits present diffusely throughout the retina, with progressive vessel attenuation (Figs. 64.2a–c and 64.3a, b) [16, 17]. Kajiwar et al found their patients to have a predominant rod photoreceptor degeneration [18].

PRPH2 mutations can also cause macular pattern dystrophies, which are a diverse group of diseases characterized by deposits, pigment, and/or atrophy in the macula [19–22]. *PRPH2* mutations have been associated with adult-onset foveomacular vitelliform dystrophy (AOFVD), butterfly-shaped pattern dystrophy, and multifocal pattern dystrophy resembling *ABCA4*-related disease [23–25]. Onset of disease is variable, but many patients are asymptomatic until their 50s

[5]. Central vision is lost gradually with time; many patients (up to 50%) exhibit severe vision loss because of atrophy or choroidal neovascularization [5, 20]. Fluorescein angiography can be helpful in distinguishing between different types of pattern dystrophy [26]. Importantly, a dark choroid may not be observed with pattern dystrophies associated with *PRPH2* mutations [26]. AOFVD typically illustrates bilateral round yellow-white subretinal lesions with central pigmentation in the macula (Figs. 64.4, 64.5, 64.6, and 64.7). These appear bright on fundus autofluorescence (FAF) due to lipofuscin accumulation and dark on fluorescein angiography (FA) (surrounded by a bright ring) [23]. Optical coherence tomography (OCT) can be useful in delineating the lesion. AOFVD may be confused with Best vitelliform macular dystrophy but may be distinguished by a normal electro-oculogram (EOG) [23]. AOFVD typically exhibits a normal full-field ERG. In butterfly-shaped pattern dystrophy, the fundus is characterized by a spoked “butterfly-shaped” pigment deposit at the center of the macula, surrounded by depigmentation (Figs. 64.6 and 64.7) [20]. The lesion may have regions of low and high autofluorescence on FAF, while FA reveals hypofluorescence in areas with pigment deposits and elevated signal in areas with depigmentation and atrophy. Full-field ERG is usually normal, but, unlike AOFVD, color vision and the EOG are abnormal. Multifocal pattern dystrophy (MPD) resembles *ABCA4*-related disease in many ways [26, 27]. The flecks seen in MPD greatly resemble the yellow flecks in the macula and beyond the arcades frequently seen in *ABCA4*-related disease (Fig. 64.1a, b). Differences include a later onset of disease and a dominant inheritance pattern. The appearance of the macula ranges from pigmentary abnormalities and deposits to atrophy; some patients may exhibit AOFVD or butterfly lesions early in the disease course. As with *ABCA4*-related disease, flecks are hyperautofluorescent on FAF and FA (Fig. 64.1b). A dark choroid is usually not observed, but Kim et al. [28] reported one case of MPD with a dark choroid and CNV. Patients may develop atrophy at the macula, which may result in more diffuse posterior pole atrophy. MPD patients may experience night blindness, but central vision deficits

may also be present; they typically exhibit progressively deteriorating retinal function on GVF and ERG (either mixed, rod-cone or cone-rod), which is unique among pattern dystrophies [29]. As with MPD patients exhibiting vitelliform or butterfly lesions early in the disease, some patients may progress from one class of pattern dystrophy to another class; there are also reports of interocular phenotypic asymmetry.

Fig. 64.1 Color fundus photograph of the right eye from a 51-year-old female with a pattern dystrophy, showing a butterfly pattern.

PRPH2 mutations also cause CACD, in which patients present in their 30s to 40s (later with some mutations) with reduced visual acuity, metamorphopsia, or photophobia [30]. Some mutations (e.g. p.Arg172Trp) are associated with significant phenotypic variability, with variable penetrance and expressivity (with reports of cone-rod dystrophy, ADRP, and CACD observed within the same family), while others exhibit a more consistent phenotype [3, 4]. The p.Arg172Trp mutation may exhibit a worse visual prognosis than other mutations [2]. Fundusoscopic findings range from subtle pigimentary changes early in life to areas of well-defined atrophy (broken into stages I–IV) that eventually include the fovea and optic disc in the late stages. Bull’s-eye maculopathy has also been reported with CACD. As with other macular degenerative diseases, FAF and FA are useful to define the extent of retinal atrophy. FAF ranges from patchy increases in autofluorescence to hypoautofluorescent confluent areas reflecting atrophy that may resemble the late atrophic stages of dry AMD. ERG may be normal or may exhibit a cone or cone-rod pattern of degeneration in the late stages of disease. Given that this is a disease affecting the macula, multifocal and pattern ERG are frequently abnormal.

Mutation in *PRPH2* may also cause an autosomal dominant maculopathy that is similar to age-related macular degeneration (AMD) (named “AMD-like late-onset maculopathy”) [31]. Patients present during the fifth decade with reduced visual acuity and may exhibit features of dry AMD

Fig. 64.2 Case summary: 37-year-old man with a multifocal pattern dystrophy. (a) Montage color fundus photo of the right eye, showing a multifocal pattern dystrophy resembling the pisciform flecks of

Stargardt disease in the macula and along the vascular arcades. (b) Fundus autofluorescence of the right eye, showing hyperautofluorescence in the areas with fleck-like deposits.

Fig. 64.3 Case summary: 51-year-old man with retinitis punctata albescens (RPA). (a) Color fundus photograph of the right eye showing diffuse white round deposits in the fundus. (b) Fundus autofluorescence of the right eye showing areas of hypo- and hyperautofluorescence associated with the white deposits. (c) Spectral-domain optical coherence tomography of the right eye, showing an overall maintained retinal architecture without ellipsoid loss, with deposits localized to the sub-retinal space.

eye, showing areas of hypo- and hyperautofluorescence associated with the white deposits as well as hypoautofluorescence in the macula corresponding to the areas of atrophy.

Fig. 64.5 Color fundus photograph of the right eye from a 62-year-old man with pattern dystrophy, showing the late stage of a butterfly pattern and macular atrophy with hyperpigmented spots.

Fig. 64.6 Color fundus photograph of the left eye of a 51-year-old woman with a pattern dystrophy.

Fig. 64.7 Case summary: 37-year-old man with cone-rod dystrophy. (a) Color fundus photograph of the right eye, showing a macular bull's eye lesion and patchy RPE pigmentary changes within the arcades. (b)

Fundus autofluorescence of the right eye, showing hypoautofluorescence at the macula in the areas with atrophy.

(drusen, geographic atrophy, etc.) or wet AMD (CNV, hemorrhage). FAF may be useful to detect the extent of atrophy; FA is useful to reveal the exudative changes of wet AMD associated with *PRPH2* mutations.

Dominant cone-rod dystrophy has also been shown to be caused by mutations in *PRPH2* [32]. Patients present in their 20s to 40s with reduced visual acuity with or without nyctalopia, abnormal color vision, and photophobia; peripheral vision is lost gradually later in the disease course. As

with many other cone-rod dystrophies, the fundus is characterized by changes at the macula that range from mild pigmentary changes, to bull's eye maculopathy, to atrophy (Fig. 64.5a). FAF may range from patchy increases in hyperautofluorescence early in the disease to areas of hypoautofluorescence later in the disease course (Fig. 64.5b). Full-field ERG reveals a cone-rod pattern of degeneration [29]. Similar to CACD and pattern dystrophies, the pattern ERG is abnormal.

RDH12 encodes retinol dehydrogenase, which reduces 9-*cis* and all-*trans*-retinol in the retina. Mutations in *RDH12* may cause a spectrum of disease, ranging from autosomal recessive Leber congenital amaurosis (LCA), which classically begins within the first year of life, to early-onset retinitis pigmentosa (rod-cone dystrophy), which starts within the first decade [1–5]. Given the phenotypic overlap between autosomal recessive LCA and early-onset rod-cone dystrophy, it may be more useful to see these diseases as part of the same spectrum of differential disease severity. There has also been a report of autosomal dominant retinitis pigmentosa associated with a mutation in *RDH12* [6].

Homozygous or compound heterozygous mutations in *RDH12* cause about 4% of LCA, in which patients present with poor vision within the first year of life [1, 6]. Visual acuity is reduced at an early age, and some patients may exhibit nyctalopia, pendular nystagmus, early-onset posterior subcapsular cataracts, and/or color vision abnormalities. Walia et al. reported that these patients exhibit visual acuities ranging from 20/63 to 20/200 (average 20/125) [7]. These patients exhibit extensive mid-peripheral bone spicule pigment deposits, RPE atrophy, waxy pallor of the optic disc, and retinal vessel attenuation (Fig. 65.1a). Some patients may have a “beaten bronze” appearance of the fundus or macular atrophy (Figs. 65.2a, 65.3a, and 65.4a) [6]. The ERG has been reported to become non-recordable at as early as 4 years of age in one study and reveals severe pan-retinal dysfunction in both rods and cones when recordable [8]. GVF may reveal defects ranging from no residual visual field, only temporal islands remaining, or a central scotoma with scattered surrounding scotomata. A monocular Coats-like reaction has been reported in some patients [1, 9].

Some patients may present within the first decade with a clinical picture resembling early onset RP [2, 6, 10]. These patients experience nyctalopia (19% overall) [10] and visual field constriction (22% overall) [10] at an early age, which progress with time. Visual acuity in these patients is typically better than patients with the LCA phenotype described above and may exhibit mild improvement before deteriorating further [2, 10]. Walia et al. [7] reported the median VA in these patients to be 20/80 (at a mean age of 18), with 87.5% of patients having acuities better than 20/200. Fundus findings feature peripheral pigment deposits that eventually progress to a large area of macular atrophy later in the disease process. Cystoid macular edema (CME) and optic atrophy have been reported [11]. Some patients may exhibit para-arteriolar sparing of the retinal pigment epithelium [10]. FAF reveals hypo-autofluorescence in areas of atrophy, such as the macula, but may also exhibit foveal hyperautofluorescence in some patients; the intervening areas between atrophic regions and the peripapillary region may also exhibit hyperautofluorescence (Figs. 65.2b, 65.3b, and 65.4b) [10]. Optical coherence tomography is helpful to visualize the extent of photoreceptor and retinal pigment epithelium loss (Fig. 65.2c and 65.3c). Full-field ERG shows severely reduced values in both rod and cone parameters when recordable [9]. GVF usually reveals bilateral constriction of peripheral fields [9], but some patients may show central scotomas or undetectable fields [8].

Autosomal dominant retinitis pigmentosa has also been reported with a mutation in *RDH12* [12]. Patients in this family presented at an average age of 28, ranging from 12 to 43 years. Visual acuity was maintained into the eighth decade. Fundus findings featured classical RP, with diffuse peripheral to mid-peripheral bone spicule deposits and RPE atrophy, vessel attenuation, and macular sparing.

Fig. 65.1 Color fundus photograph of the left eye from a 28-year old woman with a history of juvenile-onset RP, demonstrating optic disc pallor, vessel attenuation, macular atrophy, and peripheral pigment deposition (densest in the mid-periphery outside the arcades).

Fig. 65.2 Case summary: 11-year-old male with Leber congenital amaurosis (**a**) Color fundus photograph of the right eye, showing retinal pigment epithelium atrophy in the macula and outside the arcades and beaten bronze appearance of the macula. (**b**) Fundus autofluorescence, showing radial hypoautofluorescent regions in areas of RPE atrophy, each with a surrounding band of hyperautofluorescence. There is also

foveal hyperfluorescence, as well as hyperfluorescence in the residual RPE around the optic nerve head. (**c**) Spectral domain-optical coherence tomography (SD-OCT), showing extensive loss of the ellipsoid zone (EZ) and the outer nuclear layer (ONL) band, as well as a faint epiretinal membrane, with hyperreflective deposits above the RPE.

Fig. 65.3 Case summary: 27-year-old with LCA, onset at birth, visual acuity 1.6 logMAR (20/800 Snellen). (a) Color fundus photograph of the right eye, showing retinal vessel attenuation, extensive chorioretinal atrophy in the macula (with staphyloma), atrophy outside the arcades with bone spicule pigment deposits, as well as peripapillary atrophy. (b) Fundus autofluorescence imaging shows diffuse hypoautofluorescence

regions in areas of atrophy (including the macula), with residual autofluorescence in the intervening regions. There is also hyperfluorescence in the residual RPE around the optic nerve head outside the area of peripapillary atrophy. (c) Spectral domain-OCT of the macula, showing a staphyloma in the setting of extensive outer retinal atrophy, with loss of the EZ and ONL band as well as the RPE band in some areas.

Fig. 65.4 Case summary: 3-year-old Hispanic female (CEI24625). (a) Color fundus photograph of the right eye, showing retinal vessel attenuation, macular atrophy with pigment deposition, RPE depigmentation and atrophy inside and outside the arcades, and peripapillary atrophy. (b) Fundus autofluorescence, showing diffuse hypoautofluorescence

regions in areas of atrophy (including the macula), with residual autofluorescence in the intervening regions. Again, there is hyperautofluorescence at the border of the residual RPE around the optic nerve head surrounding the area of hypoautofluorescent peripapillary atrophy.

RDH5 encodes retinol dehydrogenase, which catalyzes the conversion of 11-cis retinol to 11-cis retinal in the final step in the synthesis 11-cis retinaldehyde, the chromophore in visual pigments. Mutations in *RDH5* cause fundus albipunctatus (FA), which follows an autosomal recessive pattern of inheritance.

Initial symptoms start in early childhood and usually begin with complaints of impaired dark adaptation and nyctalopia [1]. Most patients have good visual acuities, which are usually 20/30 or better. Fundus examination reveals the presence of extensive fine white dots extending to the mid-periphery of the retina, usually excluding the macula (Fig. 66.1a) [2–4]. Cone and macular dystrophies are generally observed in older patients later in the disease course. In one study, however, a 9-year-old patient with FA exhibited symmetric atrophic macular lesions in both eyes [5]. These white dots typically have very discrete borders and may range in size from 50 to 150 μm in diameter. In general, fundus autofluorescence imaging varies, sometimes showing a localized crescent or bull’s-eye pattern with macular hypoautofluorescence (Fig. 66.1d) [6–8]. In younger patients, fundus autofluorescence imaging may reveal hyperautofluorescent spots, which correlate with the retinal white dots, though not all fundoscopic white dots autofluoresce [5]. Some patients may also have a ring of hyperautofluorescence

surrounding the fovea [6]. It is important to note that the overall autofluorescence signal is lower than in that of control patients, which may reflect reduced lipofuscin in the outer retina as a result of the pathway defect in *RDH5* mutations, similar to LCA caused by mutations in *RPE65*, *LRAT* or vitamin A deficiency [6, 8]. Given this limitation, infrared reflectance (IR) imaging has been reported to be useful in revealing greater detail. IR imaging has been reported to better reveal the hyper-reflective dots that correspond to white dots seen on fundoscopy [7]. SD-OCT demonstrates triangular-shaped deposits corresponding to the white dots seen on fundus exam, which extend from the Bruch’s membrane through the ellipsoid zone and even the external limiting membrane (Fig. 66.1c, e) [6–8]. These deposits are notably different from the dome-shaped deposits seen in retinitis punctata albescens. ERG responses are usually mildly diminished for both photopic and scotopic parameters, although prolonged dark adaptation will result in improvement of the scotopic responses (Fig. 66.1b) [3, 4, 6, 7, 9]. Scotopic bright flash ERG may have a b:a ratio low enough to be classified as a negative ERG [6]. One study observed that 38% of patients with FA exhibit extensive cone dysfunction and that cone-ERG b-wave amplitudes tend to decline with increasing age [10].

Fig. 66.1 Case summary: 10-year-old female (CEI25381) with fundus albipunctatus. **(a)** Color fundus photograph of the right eye, showing typical findings of fundus albipunctatus, with extensive fine

white dots extending from the arcades to the mid-peripheral retina. **(b)** Full-field electroretinogram of the right and left eyes, showing mildly diminished photopic and scotopic parameters.

Fig. 66.1 (continued) (c) Spectral domain-optical coherence tomography (SD-OCT) of the right eye at age 10, showing the white dots as hyperreflective lesions in the subretinal space. (d) Fundus autofluorescence of the right eye at age 12 years, showing overall reduced

retinal autofluorescence, with numerous discrete foci of hyperautofluorescence corresponding to the white dots around the vascular arcades. (e) Spectral domain-OCT of the right eye at age 15 years, showing subretinal deposits corresponding to the white dots.

RHO encodes rhodopsin, which is the visual pigment found in rod photoreceptors. Pathogenic mutations have been associated with autosomal dominant retinitis pigmentosa (ADRP), including sectoral RP, with autosomal dominant congenital stationary night blindness (CSNB), and, rarely, with autosomal recessive RP. *RHO* mutations are the most common cause of ADRP, accounting for 25–30% of ADRP. p.Pro23His is the most frequently identified mutation in *RHO* in the USA [1, 2].

Patients with *RHO*-associated ADRP typically complain of difficulties with night vision and peripheral vision, with onset in the second-to-fourth decades [3, 4]. Fundoscopic features include the typical bone-spicule pigmentation seen in RP, which, when not generalized, is most commonly seen confined to the inferior retina (sectoral RP) (Figs. 67.1a–c, 67.2a, and 67.3a). Sectoral RP is associated with a milder visual deterioration, with patients occasionally being asymptomatic and identified at routine examination [5]. Loss of visual field generally precedes declines in visual acuity [6, 7]. There are over 150 *RHO* pathogenic variants identified to date [8], with some known genotype-phenotype correlations. For example, the p.Pro23His variant is

associated with a relatively mild but variable phenotype [9]. Electroretinography (ERG) usually shows a rod-cone pattern that progresses to broader retinal dysfunction with time. Fundus autofluorescence imaging may exhibit a hyperautofluorescent perifoveal ring that progressively constricts over the course of disease (Figs. 67.2b and 67.3b) [10]. Optical coherence tomography may show cystoid macular edema as well as the extent of outer retinal atrophy (Figs. 67.2c and 67.3c).

Infrequently, autosomal recessive RP may be caused by mutations in *RHO*. Carriers are asymptomatic but have mildly abnormal scotopic ERGs.

Dominantly-inherited CSNB may also be caused by certain mutations in *RHO* [11]. These patients typically experience nyctalopia from infancy but maintain relatively good central visual acuity and color vision. Fundoscopy usually reveals a normal fundus. Patients may have electrophysiological evidence of inner retinal rod system dysfunction (electronegative ERG in response to a bright white flash in the dark-adapted eye, with a reduced b-wave-to-a-wave ratio) in association with normal cone ERGs.

Fig. 67.1 Case summary: Fifty-four-year-old man with sectoral RP. (a) Color fundus photograph of the right eye, showing inferior RPE atrophy with bone spicule pigment deposits extending to the inferior arcades. (b) Fundus autofluorescence of the right eye, showing hypoautofluorescence in the inferior retina extending peripherally from

the inferior arcades; this area corresponds to the area of atrophy and bone spicule pigment deposition. There are also foci of hypoautofluorescence in the temporal and superior macula, as well as a streak of hyperautofluorescence across the inferior macula. (c) Goldman visual field testing, showing sectoral loss of visual field.

Fig. 67.2 (a) Color fundus photograph of the left eye from a 13-year-old boy, showing an essentially unremarkable fundus. (b) Fundus autofluorescence of the left eye, showing a macular hyperautofluorescent

ring in the parafovea. (c) Spectral domain-optical coherence tomography of the macula, showing cystoid macular edema.

Fig. 67.3 (a) Color fundus photograph of the right eye from the 48-year-old father of the 13-year-old boy in Fig. 67.2, showing extensive peripheral atrophy, with bone spicule pigment deposits extending from the periphery to the vascular arcades. There is also abnormal pigmentation without obvious atrophy in a ring surrounding the fovea. (b) Fundus autofluorescence of the right eye, showing a macular hyperau-

tofluorescent ring surrounding the fovea that appears more constricted than that seen in Fig. 67.2b. There are extensive areas of hypoautofluorescence outside the arcades corresponding to the areas of atrophy. (c) Spectral domain-OCT, showing loss of the outer nuclear layer and ellipsoid zone, with foveal-sparing.

RIMS1 encodes Rab-3 interacting molecule, which is a photoreceptor synaptic protein involved in regulating vesicle exocytosis. Mutations in *RIMS1* are associated with autosomal dominant cone-rod dystrophy (CORD7) [1, 2].

RIMS1-related CORD7 has a variable age of onset, ranging from the second to the fifth decade of life. Patients initially experience deterioration in central vision, with subsequent nyctalopia. Some patients may experience mild photophobia. Visual acuity varies from 20/20 to 20/400. Fundus changes range from mild RPE disturbance to extensive atrophy and pigmentation in the macula but may also

involve the periphery in some patients (Fig. 68.1a). Vessel attenuation and bull's eye maculopathy (BEM) may also be observed (Fig. 68.2a). Fundus autofluorescence (FAF) imaging may reveal (i) areas of reduced FAF corresponding to atrophy seen clinically, (ii) a BEM appearance, and/or (iii) a perifoveal ring of increased FAF (Fig. 68.2b, c) [1]. This ring of increased FAF may enlarge with time, with the size of the ring correlating with age. FAF imaging may be helpful to identify young pre-symptomatic patients. Full-field ERG reveals reduced cone and rod responses, with the cone system affected to a greater extent than the rod system [2, 3].

Fig. 68.1 (a) Color fundus photos of the right and left eyes, showing macular atrophy and RPE changes in both eyes, with the appearance of bull's eye maculopathy in the left eye. (b) Fundus autofluorescence of

the right and left eyes, showing patchy hypoautofluorescence surrounding the fovea, corresponding to areas of atrophy, with a surrounding ring of hyperautofluorescence.

Fig. 68.2 (a) Color fundus photos of the right and left eyes in a different patient, showing macular bull's eye atrophy changes. (b) Fundus autofluorescence of the right and left eyes, showing hyperautofluorescent rings surrounding the foveae. (c) Fundus autofluorescence of the right eye at follow-up, showing foveal hyperautofluorescence with surrounding patchy hypoautofluorescence in areas corresponding to atrophy; a patchy hyperautofluorescent ring surrounding the fovea can still be appreciated.

RLBP1 (also known as *CRALBP*) encodes cellular retinaldehyde-binding protein, which acts primarily as an acceptor of 11-*cis* retinal during the isomerization step of the visual cycle. Mutations in *RLBP1* cause Bothnia retinal dystrophy, fundus albipunctatus, Newfoundland rod-cone dystrophy, and retinitis punctata albescens [1].

The retinal phenotype is similar to most forms of Retinitis Pigmentosa (RP; rod-cone dystrophy), although there may be marked variation in severity between affected individuals. Three early-onset forms of autosomal recessive RP caused by mutations in the *RLBP1* gene are associated with multiple white deposits at the level of the RPE. One of these is retinitis punctata albescens, while the other two have been described in genetic isolates from North-Eastern Canada (Newfoundland rod-cone dystrophy) and Northern Sweden (Bothnia dystrophy).

RLBP1-related retinitis punctata albescens (RPA) follows an autosomal recessive pattern of inheritance. Patients have early onset (usually in the first decade of life) of nyctalopia. Best corrected visual acuities (BCVA) are typically 20/20 or better [2]. Fundoscopy reveals round punctate white deposits throughout the entire retina (Fig. 69.1a) [2–4]. Pigment mottling, hypopigmentation, arteriole attenuation, waxy disc pallor, and blunted foveal reflexes may also be seen in older patients [2]. Fundus autofluorescence may show a reduction of overall autofluorescence, with hyperautofluorescent foci corresponding to the white subretinal deposits (Fig. 69.1b). Optical coherence tomography (OCT) may reveal diffuse retinal thinning in the macular area, particularly in the outer nuclear layer, and may show subretinal hyperreflective lesions corresponding to the white deposits in the earlier stages of disease (Fig. 69.1c) [4]. Electroretinogram (ERG) may show significantly reduced rod and cone responses, with a predominant loss of rod function [3, 5].

RLBP1-related fundus albipunctatus is characterized by symmetrical white dots in the fundus, with higher concentrations in the mid-periphery, which is similar to the irregular white deposits of RPA (Fig. 69.1a). Initial symptoms begin in early childhood with nyctalopia and dim-light vision

difficulties. Visual acuities may vary, ranging from 20/40 to 20/200, but younger patients may be less affected [6, 7]. Fundus photography typically shows multiple round white deposits (about 100–125 μm in diameter) in the mid-peripheral retina. At early ages, the central macula is usually spared of dots, but at later ages the deposits may be prominent in the major vascular arcades (Fig. 69.1a) [7]. In the fifth-to-sixth decades of life, optic disc pallor, arteriole attenuation, bone spicules, and atrophy may also be observed [7]. Electroretinography reveals low or nonrecordable scotopic readings and low photopic responses with slightly prolonged implicit times [6, 7].

Bothnia dystrophy (BD) is an atypical variant of autosomal recessive retinitis pigmentosa (RP). Individuals with *RLBP1*-related BD typically have an onset of nyctalopia in their early childhood [8]. Visual acuities often deteriorate to legal blindness with disease progression. Vision loss often starts in the second decade of life, with evidence of paracentral and central scotomas [8]. Fundoscopy may reveal extensive white-yellow spots similar to those found in retinitis punctata albescens. The midperiphery may have a mottled appearance, and there may be circular confluent atrophic areas (especially in later stages of disease). Macular atrophy reminiscent of central areolar atrophy may also be found in patients after the third decade of life [8]. OCT may show general retinal thinning at the fovea, surrounding the fovea, and in areas of the outer macula; RPA-like deposits are usually visualized at the level of the RPE (Fig. 69.1c) [9, 10]. ERGs typically show non-recordable scotopic responses and prolonged dark adaptation [10, 11].

Newfoundland rod-cone dystrophy (NFRCD) is similar to RPA and BD but with a younger age of onset and a more rapid progression [1]. Nyctalopia is typically present from birth or infancy. From childhood to the second-to-fourth decades of life, patients experience progressive loss of peripheral, central, and color vision, with early maintenance of visual acuity. Goldman visual field testing may reveal a ring scotoma close to fixation instead of in the midperipheral field (where it is often found in typical RP). The ring sco-

Fig. 69.1 (a, b) Color fundus photograph of the right eye from a 6-year-old female patient, showing multiple round white deposits around the arcades, with macular-sparing. (c) Fundus autofluorescence of the left eye, showing an overall reduction of autofluorescence, with foci of hyperautofluorescence corresponding to the white deposits

shown in (b). (d) Spectral domain-optical coherence tomography of the right and left eyes, showing generally maintained retinal cross-sectional architecture without atrophy, as well as a subretinal hyperreflective lesion in the temporal macula of the left eye.

toma may become a complete central scotoma with disease progression. Color vision abnormalities may be found initially as mild protanomaly/deutanomaly and/or tritanomaly, but these typically progress to eventual loss of color perception. Funduscopy may reveal a normal fundus or mild arteriolar attenuation until later in the disease

progression, when there may be macular atrophy with a “beaten bronze” appearance [1]. In young patients, a perimacular ring of white stippling may be observed, along with scalloped-bordered lacunar atrophy of the midperipheral RPE over time (similar to that seen in gyrate atrophy, but without elevated ornithine levels) [1]. ERG scotopic

responses may be low in young patients, while both scotopic and photopic responses may be extinguished later in the disease process.

RP1 encodes oxygen-regulated protein 1, which is involved in photoreceptor development, the organization of photoreceptor outer segments, and the regulation of photoreceptor microtubules. Mutations in *RP1* cause autosomal dominant retinitis pigmentosa (ADRP) (rod-cone dystrophy), often associated with a relatively good prognosis [1–5]. There have also been reports of *RP1* mutations that cause autosomal recessive RP [6–8].

Patients with ADRP often present in their early twenties with complaints of night blindness and/or peripheral field loss, though some patients may present as late as in their 50s. Good visual acuity is usually maintained until late in the disease course. Patients with dyschromatopsia are more likely to exhibit worse visual acuity. Patients may develop cataracts at an earlier age (often posterior subcapsular) or develop cystoid macular edema (CME). Fundus examination usually demonstrates typical findings of RP (Figs. 70.1a–c and 70.2a). Fundus autofluorescence reveals areas of RPE atrophy, which may be present in the periphery outside the arcades or in the macula (sometimes with patchy hypoautofluorescence at the macula). Full-field ERG usually reveals both rod and cone dysfunction, usually in a rod-cone pattern. Multifocal ERG usually shows maintained responses at the centrally-located hexagons. GVF reveals a rod-cone pattern of degeneration with constricted fields. OCT may show

maintained macular retinal lamination, although some patients exhibit thinning at the macula, loss of the outer nuclear layer (ONL), or cystoid macular edema (CME) (Fig. 70.2b). Incomplete penetrance and variable expressivity have been reported in patients with *RP1* mutations and result in phenotypic variability with respect to disease onset, fundus features, visual acuity, visual fields, and ERG findings (Figs. 70.1a–c and 70.2a) [3, 9, 10]. Monocular disease, with the contralateral eye exhibiting a completely normal fundus and full-field ERG, has been reported in one patient with a mutation in *RP1* [11].

Patients with certain homozygous or compound heterozygous mutations in *RP1* may exhibit autosomal recessive retinitis pigmentosa [6, 7]. These patients typically present early in childhood with nyctalopia and rapidly lose vision by the second decade of life. Fundus findings may feature optic disc pallor, vessel attenuation, macular stippling, and bone-spicule deposits in the mid-periphery, but these are not universal findings. The full-field ERG is often non-recordable or shows severe loss of both rod and cone function. Carriers of these mutations usually have no symptoms or signs of disease.

Of note, homozygosity of the p.N985Y variant at the *RP1* locus has been associated with an elevated risk of hypertriglyceridemia, though the mechanism and clinical significance of this association are unknown [12].

Fig. 70.1 Color fundus photographs from three different patients with *RP1* mutations, showing different variations and degrees of typical findings of retinitis pigmentosa (RP), including optic nerve pallor, retinal

vascular attenuation, and peripheral atrophy with bone spicule pigment deposits. (a) Right eye from a 23-year-old male patient. (b) Left eye from a 24-year-old female patient. (c) Left eye from a 56-year-old male patient.

Fig. 70.2 Case summary: 6-year-old boy with compound heterozygous mutations and early-onset RP. (a) Color fundus photograph of the right eye, showing typical findings of RP. (b) Spectral domain-optical

coherence tomography at age 7, showing foveal preservation and outer retinal degeneration (loss of the ellipsoid zone and outer nuclear layer) outside the fovea.

RP2 encodes a protein that localizes to the base of photoreceptor cilia and is thought to be involved in cellular transport regulation. *RP2* mutations are responsible for 10–20% of X-linked retinitis pigmentosa (XLRP) [1, 2].

Broadly, XLRP has an earlier onset than dominant or recessive RP [3]. Patients present within the first decade of life with night blindness and reduced visual acuity [2, 4]. Visual acuity typically deteriorates to worse than 20/200 as early as the third decade. Several studies have noted high myopia [4, 5]. Funduscopy findings usually show more severe disease at the macula than at the peripheral retina when compared to retinitis pigmentosa caused by other genes. The appearance of the macula varies greatly: it may be normal or may show granular changes, bull's-eye atrophy, perimacular atrophy, or generalized macular atrophy (Figs. 71.1, 71.2, 71.3, 71.4, and 71.5) [4, 6]. Optic disc pallor and atrophy (either peripapillary or temporal) are often observed (Figs. 71.1 and 71.2). The peripheral retina may exhibit granularity, depigmentation, variable degrees of

pigment deposits, or chorioretinal atrophy (Figs. 71.1 and 71.2). Tapetal sheen, which is commonly seen in *RPGR* mutations, has not been reported in patients with *RP2* mutations. ERG usually exhibits a rod-cone pattern of degeneration, although a cone-rod pattern has been reported [4]. GVF reveals central scotomata in up to 50% of patients and is often observed in patients younger than 12. Most patients exhibit constricted peripheral fields. Superior field loss (also seen in patients with *RHO* mutations) has been reported as well. Studies comparing the phenotype to *RPGR* have shown that patients with *RP2* mutations generally have worse visual acuity when adjusted for age but no significant difference in dark adaptation thresholds, visual field area, or ERG [7].

Some patients have been reported to exhibit choroideremia-like peripheral retinal atrophy with no pigment deposits (Figs. 71.1 and 71.4) [4].

Manifesting carriers may also exhibit a wide range of signs of disease, including myopia, macular atrophy, reduced visual acuity, asymmetrical disease, and central scotomas [4].

RPE65 encodes retinoid isomerase, which generates (and regenerates) 11-*cis* retinal in the RPE as part of the canonical retinoid visual pathway [1]. Mutations in *RPE65* cause early-onset autosomal recessive retinitis pigmentosa (rod-cone dystrophy), Leber Congenital Amaurosis (LCA), and Severe Early Childhood Onset Retinal Dystrophy (SECORD) [2]. *RPE65* mutations may also cause dominantly inherited RP [3]. Sequence variants in *RPE65* have also been identified in patients with a retinal appearance similar to Fundus Albipunctatus [4].

RPE65 mutations account for 3–16% of LCA and SECORD, with LCA characterized by poor vision beginning within the first year of life and SECORD before age 5 [5, 6]. Patients with LCA tend to exhibit poor visual pursuit, roving eye movements, reduced or absent pupillary responses, and nystagmus. Night blindness may be noted in some infants. Patients with LCA exhibit poor visual acuity from infancy. The fundus may be normal at birth, but patients may exhibit RPE mottling or granularity at the macula or periphery, RPE thinning, vessel attenuation, and peripapillary loss of pigmentation; some patients may exhibit macular atrophy later in life (Figs. 72.1, 72.2, 72.3a, and 72.4). The ERG is usually non-recordable in LCA, and GVF reveals gradual concentric loss of peripheral fields. The full-field stimulus test (FST) can detect sensitivity to specific light stimuli and determine the presence of residual rod and cone function in patients [10–12]. Fundus autofluorescence usually reveals hypoautofluorescence due to lack of production of chromophores [13, 14], though some studies have reported reduced autofluorescence in patients with hypomorphic mutations [9]. Foveal hyperautofluorescence may also be observed (Fig. 72.3b).

Two percent of recessive RP is caused by mutations in *RPE65* [2]. This diagnosis is part of a spectrum that includes LCA and has been given to those presenting in early childhood (Severe Early Childhood Onset Retinal Dystrophy) but not as early as LCA. Many of the symptoms described above

may be present in these patients as well. Night blindness is a prominent symptom early in life in these patients, and they generally have better visual acuity (20/50 to LP; median 20/80) than those with LCA [15–17]. Patients with SECORD retain measurable visual acuity in the first/second decades and sometimes beyond, with slow progressive loss over time [7]. Several studies have reported improvement in visual acuity for a period of time in association with SECORD [7, 8]. Nystagmus early in life is common; photophobia is uncommon in these patients, though some patients may develop it later in life [7, 18]. Fundus findings range from RPE granularity to optic disc pallor, peripapillary hypopigmentation, retinal vascular attenuation, and peripheral circular patches of atrophy and macular atrophy. Bone spicule deposits may be observed but are uncommon in these patients (Fig. 72.4). Weleber et al. [8] reported that some patients with *RPE65* mutations display discrete intraretinal fine white dots with chorioretinal atrophy. The ERG may reveal a rod-cone pattern of degeneration in patients with a recordable full-field ERG. One study described a patient who presented within the first year of life with poor vision, nystagmus, and non-recordable ERG, suggestive of a diagnosis of LCA, who maintained good central visual acuity into their late teens, highlighting the overlap between these two disease entities [8]. A milder phenotype may be associated with residual activity from hypomorphic alleles [9]. One study showed that the majority of loss of visual acuity and field occurs during the mid-teenage years (Fig. 72.3c) [7].

A dominantly-acting *RPE65* mutation was reported in a family with RP with involvement of the choroid [3]. Patients in this family presented in their second-to-fifth decades with night blindness and poor dark adaptation. As the disease progressed, peripheral vision was gradually lost. Fundus findings ranged from mid-peripheral bone-spicule or nummular pigment deposits and RPE thinning to diffuse outer retinal atrophy. The ERG showed a rod-cone pattern of degeneration.

Fig. 72.1 Color fundus photograph of the left eye from a 2-year-old girl with Leber congenital amaurosis (LCA), showing macular retinal pigment epithelium (RPE) granularity and a choroideremia-like fundus.

Fig. 72.2 Color fundus photograph of the right eye from a 22-year-old woman diagnosed with Severe Early Childhood Onset Retinal Dystrophy (SECORD) at the age of 3. Fundus images show intraretinal white dots in the periphery, macular atrophy, and midperipheral RPE granularity, with sparse bone spicule pigment deposits in the periphery.

RPGR encodes retinitis pigmentosa GTPase regulator, which plays a role in photoreceptor ciliary function. Mutations in *RPGR* are inherited in an X-linked manner and have been shown to cause X-linked retinitis pigmentosa (XLRP), cone/cone-rod dystrophy, and macular dystrophy [1, 2]. Sequence variants in *RPGR* account for approximately 70–80% of XLRP. *RPGR* exhibits significant phenotypic variability, which partly results from two predominant alternatively-spliced isoforms [Exons 1–14 and Open Reading Frame 15 (ORF15)] that can each harbor mutations [3]. However, the vast majority of mutations are located in ORF15.

XLRP has an earlier onset and more rapidly progressive natural history than many other forms of retinitis pigmentosa (RP). Studies have shown that patients with mutations in *RPGR* experience a more rapid deterioration than patients with mutations in *RHO* [4]. Broadly, studies have suggested that mutations in ORF15 are associated with greater phenotypic variability than are mutations in other regions of *RPGR* [4–6]. Male patients usually present in childhood with nyctalopia and reduced peripheral vision. This progresses over time to involve central vision, with severe visual acuity loss between ages 30 and 50 [7]. Many patients exhibit myopia. Male patients have typical fundus findings of RP. Fundoscopically, this corresponds to mid-peripheral bone-spicule deposits that progressively increase with time with increasing peripheral atrophy; retinal vascular attenuation, tapetal reflex, and optic disc pallor are also commonly observed (Fig. 73.1a) [8]. Patients often show severely reduced or absent full-field electroretinography (ERG) at presentation. Carrier females are usually asymptomatic. Although some carriers may be mildly affected, they are rarely severely affected. Carrier status can often be determined with clinical examination, fundus autofluorescence imaging, or electrophysiological testing.

There is some degree of genotype-phenotype correlation, with sequence variants at the 3'-end of *RPGR-ORF15* more often associated with a cone/cone-rod phenotype and 5' variants associated with a rod-cone phenotype. Patients with

cone-rod dystrophy present with reduced visual acuity, abnormal color vision, and photophobia [9]. They experience progressive deterioration in central vision over time, with later rod involvement, nyctalopia (occurring 5–10 years after onset of initial reduced visual acuity), and peripheral visual field loss. In contrast, patients with cone dystrophy have isolated cone dysfunction [9–11]—a far less frequently observed phenotype, since the vast majority of patients develop rod involvement over time, resulting in significant overlap between cone dystrophy and cone-rod dystrophy [12]. Fundus abnormalities are typically confined to the macula, ranging from mild retinal pigment epithelium (RPE) changes to bull's-eye maculopathy and macular atrophy (Fig. 73.2). Peripheral changes are less common, but they have been observed in older patients, consisting of typical signs associated with RP. A parafoveal ring of increased autofluorescence on fundus autofluorescence imaging can be observed in both RP and cone-rod dystrophy associated with *RPGR* (Fig. 73.1b). This hyperautofluorescent ring has been shown to constrict over time in rod-cone dystrophy and expand over time in cone-rod dystrophy, allowing it to be a marker of disease progression with prognostic implications [11, 13, 14]. Optical coherence tomography is helpful in visualizing the extent and distribution of photoreceptor and RPE loss (Fig. 73.1c).

RPGR mutations have also been reported to cause “atrophic macular degeneration” [15]. Patients present in their 20s to 40s with reduced visual acuity without symptoms of peripheral visual field loss or nyctalopia. Myopia is commonly observed. Fundoscopy is characterized by localized macular RPE atrophy in both eyes with normal peripheral retina and vasculature. Full-field ERG is usually within normal limits, although it may be reduced in a minority of patients. Goldmann visual field testing exhibits a central scotoma with normal peripheral fields.

RPGR mutations may be associated with significant intra- and inter-familial phenotypic heterogeneity [7, 11, 16, 17]. Walia et al. and Zahid et al. described siblings who exhibited discordant phenotypes (cone-rod vs. rod-cone) despite

Fig. 73.1 Case summary: 8-year-old male with X-linked retinitis pigmentosa (XLRP) associated with a mutation in *RPGR*. (a) Widefield color fundus photo of the right eye, showing diffuse retinal atrophy. (b) Widefield fundus autofluorescence imaging of the right

eye, demonstrating a hyperautofluorescent ring centered in the macula. (c) Spectral Domain Optical Coherence Tomography of the right eye, showing loss of the ellipsoid zone peripherally and presence of microcysts.

harboring the same mutation [18, 19]. Some studies have reported *RPGR* mutations in families thought to have dominantly-inherited disease, highlighting the importance of considering X-linked inheritance even when females are also affected [20]. X-linked inheritance should be considered in both isolated male cases and in any family where males are more severely affected than females. *RPGR* variants can also be associated with syndromic inherited retinal disease, with signs and symptoms of systemic ciliary dysfunction, including respiratory problems, deafness, and infertility [21, 22].

RPGRIP1 encodes X-linked retinitis pigmentosa GTPase regulator-interacting protein 1, which is important for the function of RPGR and plays a role in photoreceptor disc morphogenesis. Autosomal recessive mutations in *RPGRIP1* cause about 5% of Leber congenital amaurosis (LCA) as well as cone-rod dystrophy [1–4].

Patients with LCA usually present within the first year of life with poor vision, nystagmus, roving eye movements, poor fixation to light, and the oculo-digital sign [5]. Photophobia is more common than night blindness at an early age [5–7]. In a cohort of four Pakistani families with mutations in *RPGRIP1*, night blindness and photoaversion were reported in 38% and 31% of patients, respectively [8]. Patients are often hyperopic [6, 7]. Cataracts and keratoconus are usually observed in older patients [5, 7, 8]. Visual acuity may range from 20/400 to CF [6], but it often deteriorates to LP or NLP within the first decade [7]. McKibbin et al. [5] reported a visual acuity range of 20/200 to LP in four families [8]. The full-field ERG is usually non-recordable at an early age. Fundus abnormalities may be limited to mild vessel attenuation at an early age, but they eventually include optic disc pallor, RPE mottling, and peripheral pigment deposits in the second or third decade (often in a bone-spicule pattern, but may be nummular) [5, 9]. White drusen-like deposits have been reported in some patients [7]. The foveal structure may be normal in younger patients [7, 8]. Macular atrophy develops later in the disease course, often not until the third decade [8]. FAF may show macular loss of autofluorescence [5]. OCT imaging may reveal normal retinal architecture or show maintained

thickness at the fovea and peripheral retina with reduced thickness in the parafovea [9]. Developmental delay has been reported in some patients with LCA caused by *RPGRIP1* mutations [5].

In keeping with other genetic loci causing LCA, there is phenotypic variability in LCA caused by *RPGRIP1* mutations. Some patients may have an early-onset rod-cone dystrophy. One patient reported visual difficulties since childhood but experienced more nyctalopia and peripheral vision loss along with loss of visual acuity [10]. The patient had horizontal nystagmus and a fundus characterized by optic disc pallor, attenuated vessels, and peripheral pigmentary changes. GVF revealed only central islands of vision remaining (rod-cone pattern). OCT in this patient showed maintained foveal architecture with atrophy in the para- and perifoveal regions. In another study, visual acuity of 0.1 (\approx 20/25) at age 15 was reported in a patient with an onset of 2 years of age and a history of nyctalopia and poor color vision. This patient exhibited macular atrophy and a severely reduced ERG [4].

RPGRIP1 mutations have also been reported to cause autosomal recessive cone-rod dystrophy in two consanguineous Pakistani families [3]. These patients experienced photophobia beginning early in childhood, with color blindness and gradual loss of central vision. Hameed et al. [3] report a rapid loss of visual acuity to 20/1200 in the mid-teenage years. Fundus features include granularity and macular atrophy (sometimes in a bull's-eye pattern). Full-field ERG revealed a cone-rod pattern of degeneration (Fig. 74.1).

Fig. 74.1 Case summary: 17-year-old patient with *RPGRIP1*-associated Leber congenital amaurosis, onset at birth, and hand motion visual acuity. **(a)** Color fundus photograph of the right eye, showing a hyperemic disc, attenuated vessels, peripheral pigmentary changes, and

retinal pigment epithelium atrophy most prominent along and outside the arcades. **(b)** Spectral domain-optical coherence tomography, showing a preserved ellipsoid zone (EZ) at the fovea with EZ and outer nuclear layer loss outside the fovea.

RS1 encodes retinoschisin, which is expressed in retinal photoreceptors and bipolar cells and plays a role in the organization of retinal architecture and retinal function. Mutations in *RS1* cause X-linked juvenile retinoschisis (XLRS).

Males with mutations in *RS1* may rarely present in infancy with nystagmus, but they more commonly present in childhood with mild loss of central vision. Hyperopia is common. Visual acuity may deteriorate to 20/100, but there is significant variability among patients [1–5]. Visual acuity may remain relatively stable until adulthood [6], but it has been shown to decline with age [3]. Prognosis may be good as long as retinal detachment and vitreous hemorrhage do not occur. The disease usually affects both eyes symmetrically unless complications of the disease (vitreous hemorrhage or retinal detachment) dramatically reduce vision in one eye. Fundoscopy usually reveals foveal schisis, which presents as a characteristic “spoke-wheel” pattern of foveal cysts in the macula (Fig. 75.3a). The macular findings may progress to atrophy in later stages of the disease (Figs. 75.1, 75.2, and 75.4a, b). Peripheral retinal abnormalities, including bilateral schisis cavities (usually infero-temporal), “vitreous veils,” vascular closure, inner retinal sheen, and pigmentary retinopathy, are seen in approximately 50% of cases.

There have been reports of some patients who exhibit white flecks [7] and others who exhibit the Mizuo phenomenon (loss of the tapetal reflex with dark-adaptation and recovery with

exposure to light) [8]. FAF may provide a better illustration of the “spoke-wheel” pattern, which results from schisis at the fovea and may be associated with increased FAF (Fig. 75.3b) [5]. OCT is the most useful testing modality for diagnosis and reveals cystoid changes in the inner retina, which may wax and wane over time (Figs. 75.3c and 75.4c) [10, 11]. The retinal nerve fiber layer may be thinner in some patients than in controls [12]. Older patients may not exhibit retinoschisis on OCT, but they may have reduced macular thickness and ERM [13]. Full-field ERG testing may reveal a negative ERG, in which the b-wave to a-wave ratio is less than 1 for the scotopic b-wave, or may show prolonged implicit times for the cone flicker parameter [9, 14], while multifocal ERG (mfERG) illustrates the areas of cone dysfunction [15, 16]. Goldmann visual field testing typically shows central visual field loss (Fig. 75.4d). However, several studies have shown that the ERG may be normal, especially early in the disease course [17, 18]. About 5% of cases of XLRS are complicated by vitreous hemorrhage and retinal detachment, and these have been reported as early as the first year of life [19, 20]. Macular holes have also been reported [21].

Female carriers of *RS1* disease alleles usually do not exhibit any signs of structural or functional retinal abnormalities, although some may have abnormalities on mfERG [22], making molecular genetic testing invaluable in confirming carrier status.

Fig. 75.1 Color fundus photo of the left eye from a 26-year-old man with X-linked juvenile retinoschisis (XLRS), showing macular atrophy.

Fig. 75.2 Color fundus photo of the right eye from a 9-year-old boy with XLRS, showing macular atrophy and atrophy with pigmentation along and outside the inferior arcades and retinal periphery.

Fig. 75.3 Case summary: 12-year-old boy with a mutation in RS1. (a) Color fundus photograph of the left eye, showing macular schisis. (b) Fundus autofluorescence of the left eye, showing hyperautofluores-

cence at the fovea in areas of schisis. (c) Spectral domain-optical coherence tomography, showing schisis and segmentation of the inner retinal layers at the fovea.

Fig. 75.4 (a) Color fundus photograph of the right eye, showing macular atrophy with minimal pigmentary changes at age 48. (b) Color fundus photograph of same eye at age 78, showing an increased area of macular atrophy with significant pigment deposits. (c) Spectral domain-OCT of the same eye at age 78, showing extensive outer retinal and retinal pigment epithelium atrophy. (d) Goldmann visual field of this eye at age 77, showing dense central field loss with all three isopters.

SAG, also known as *S-antigen* or *S-arrestin*, encodes a rod photoreceptor protein involved in the recovery phase of light transduction. It is present in the retina and pineal gland and plays an inhibitory role in the activated phototransduction cascade [1, 2]. Mutations are responsible for Oguchi disease and for retinitis pigmentosa (RP).

SAG mutations are responsible for the majority of cases of Oguchi disease in the Japanese population and have an autosomal recessive pattern of inheritance. The most frequent mutation in this population is c.926delA; p.N309Tfs*12 (previously reported as 1147delA) [2, 3]. Hayashi et al. (2010) reported that 5 out of 6 Japanese patients with Oguchi disease are homozygous for the c.926delA mutation [3]. Oguchi is a form of congenital stationary night blindness (CSNB) where the only symptom is generally a childhood-onset of nyctalopia [4]. Visual acuity, visual field, and color vision are usually all within normal range. A characteristic feature of Oguchi is the diffuse golden yellow or gray discoloration of the fundus, which disappears after prolonged dark-adaptation and reappears almost immediately upon re-exposure to light (called the Mizuo-Nakamura phenomenon) [2–4]. Full-field electroretinogram (ERG) is non-recordable after 30 minutes of dark adaptation, but cone and flicker ERG recordings are essentially normal. Combined rod-cone ERG responses show a significantly reduced a-wave, a non-detectable b-wave, and well-preserved oscillatory potentials [3, 4].

SAG mutations have variable expressivity. Some patients have Oguchi disease only [2] and some manifest symptoms RP along with the Mizuo-Nakamura phenomenon [4]. There is a report of a patient with autosomal recessive RP with a

homozygous c.926delA mutation in *SAG* who has pigmentary retinal degeneration and retinal pigment epithelium (RPE) atrophy along the vascular arcades. This patient has constricted visual fields and paracentral visual field defects and also exhibits the Mizuo-Nakamura phenomenon [3].

More recently, Sullivan et al. described a dominantly-acting mutation in *SAG* (c.440G>T; p.Cys147Phe) that is responsible for 36% of the autosomal dominant retinitis pigmentosa in Hispanic patients in the United States. All these patients demonstrated classic fundus features of retinitis pigmentosa with a rod-cone pattern of ERG loss; none demonstrated the Mizuo-Nakamura phenomenon [5].

SEMA4A encodes semaphorin-4A, a cell surface receptor involved in cell-to-cell signaling, which plays a role in adaptive immunity as well as in inhibition of angiogenesis and axonal growth. One study showed that mutations in *SEMA4A* result in RPE cell susceptibility to light, oxidative, and endoplasmic reticulum stress *in vitro* [1]. Mutations in *SEMA4A* have been shown to cause autosomal recessive and autosomal dominant retinitis pigmentosa (rod-cone dystrophy) and recessive cone-rod dystrophy [2].

Patients with dominant or recessive rod-cone dystrophy present initially with night blindness and progressive peripheral vision loss, with central vision loss later in the disease process. Fundus findings include peripheral and mid-peripheral

bone spicule pigmentation with vascular attenuation; macular involvement is typically found in older patients. Optical coherence tomography may reveal foveal-sparing of photoreceptors (Fig. 77.1b).

Cone-rod dystrophy is typified by early loss of visual acuity and dyschromatopsia, with nyctalopia and peripheral vision loss occurring later; photophobia and photosensitivity are common in these patients. The fundus appears granular, with macular atrophy and peripheral pigmentation. Fundus autofluorescence may reveal increased macular autofluorescence and patchy areas of hypoautofluorescence in the mid-peripheral retina (Fig. 77.1a).

Fig. 77.1 Case summary: 52-year-old Hispanic male (CEI28386) with a family history of dominant retinitis pigmentosa with a mutation in *SEMA4A*. (a) Wide-field fundus autofluorescence of the right eye, showing increased macular autofluorescence, with patchy areas of hypoauto-

fluorescence in the mid-peripheral retina. There are also circular areas of hypoautofluorescence corresponding to RPE atrophy in the inferior retina. (b) Spectral domain optical coherence tomography of the right eye, showing extrafoveal ellipsoid zone and outer nuclear layer loss.

SNRNP200 (also known as *ASCC3L1*) encodes hBrr2, an RNA helicase essential for pre-mRNA splicing. Mutations in this gene have been associated with autosomal dominant retinitis pigmentosa (RP) [1–3].

Patients with *SNRNP200*-related RP typically present with nyctalopia, with an onset in the late first to early second decades of life. Patients exhibit a gradual decline in visual acuity and narrowing of visual fields with age, leading to eventual peripheral field loss with relatively conserved central vision. Fundoscopy may reveal waxy pallor of the optic disc, arteriolar attenuation, bone-spicule pigmentary changes

in the mid-periphery, and atrophy of the retinal pigment epithelium, which typically increases with age (Figs. 78.1 and 78.2) [1–3]. Macular atrophy may be seen in some older patients [2]. In one study, two patients in their 40s were also diagnosed with angle-closure glaucoma [1]. Full-field scotopic rod electroretinogram (ERG) may reveal reduced or non-recordable responses. In severe cases, both rod and cone function may be reduced, but in younger patients, cone cell function may be better preserved. Multi-focal ERG may display reduced signals over the entire test field or show reduction in the peripheral macula [1–3].

Fig. 78.1 Color fundus photograph from a 59-year-old woman with rod-cone dystrophy, showing typical findings of bone spicule pigmentary changes, waxy pallor of the optic nerve, and attenuation of the retinal vessels.

Fig. 78.2 Color fundus photograph from a 45-year-old man with rod-cone dystrophy, showing typical findings of retinitis pigmentosa.

SPATA7 encodes spermatogenesis-associated protein, whose retinal function is poorly defined. Autosomal recessive mutations in *SPATA7* are associated with Leber congenital amaurosis (LCA) and retinitis pigmentosa (RP).

SPATA7 mutations are a rare cause (1–2%) of autosomal recessive LCA. Patients with *SPATA7*-related LCA may have an early onset of visual symptoms, typically beginning in infancy. Similar to LCA caused by other genes, infants exhibit poor visual fixation and pupillary reflex, nystagmus, nyctalopia, hyperopic astigmatism, and transient photophobia [1–3]. In one study of 10 patients with *SPATA7* mutations, keratoconus was present in one patient, and mild cataracts were present in two patients under the age of 21 [1]. Visual acuity may present as poor as hand movements or worse, and Goldmann visual fields show less than 5° central field preservation within the first decade of life [1]. Fundus examination of patients may reveal a normal fundus at an early age or a gradually deteriorating “salt-and-pepper” appearance with atrophic retinal changes and pigment migration, with arteriolar attenuation and optic disc pallor [1, 3]. Fundus autofluorescence imaging often shows a hyperautofluorescent parafoveal ring, with hypoautofluorescence from the mid-periphery to the periphery as well as along the

arterioles. SD-OCT shows diffuse retinal thinning and preservation of the ellipsoid zone at the foveal region. ERGs in younger patients may reveal normal/subnormal rod-ERG b-wave amplitudes, but by the first decade of life, the rod ERG tends to become completely undetectable [1].

SPATA7-related early-onset retinal dystrophy has an autosomal recessive pattern of inheritance and is rare. Phenotypes are very similar to *SPATA7*-related LCA but tend to exhibit less severe disease [2]. Onset of symptoms occurs in early childhood, with complaints of vision loss and nyctalopia. Visual fields may be reduced to 5° within the first decade of life [2]. Visual acuities are normal at an early age but deteriorate over time to 20/200 to hand motion vision. Fundus examination reveals widespread RPE degeneration, arteriolar narrowing, optic disc pallor, and bone-spicule like pigmentary changes, typical of classical RP (Fig. 79.1a). Older patients may exhibit a maculopathy. Full-field ERG is typically non-recordable at an early age in both rod and cone parameters [4]. Fundus autofluorescence may show a ring of hyperautofluorescence in the macula (Fig. 79.1b), and optical coherence tomography is helpful to visualize the extent of photoreceptor and retinal pigment epithelium loss.

Fig. 79.1 Case summary: 17-year-old with *SPATA7*-associated Leber congenital amaurosis, onset at birth, hand movement visual acuity. **(a)** Color fundus photograph of the left eye, showing attenuated vessels, peripheral retinal pigment epithelium atrophy, and white retinal dots/deposits. **(b)** Fundus autofluorescence, showing a macular ring of hyperautofluorescence surrounding the fovea. **(c)** Spectral domain-optical coherence tomography, showing a broadened foveal pit with perifoveal macular loss of the ellipsoid zone and outer nuclear layer.

Mutations in *TIMP3*, which encodes an inhibitor of matrix metalloproteinase, have been shown to cause Sorsby fundus dystrophy, an autosomal dominant macular degeneration [1–4].

Patients usually present in their 40s to 50s with a sudden loss of central vision that results from choroidal neovascularization and subretinal fluid [5, 6]. Some patients experience nyctalopia before central visual deficits, but most patients are asymptomatic before sudden central vision loss. In one study, median ages of visual acuity deterioration to below 20/200 were 45 and 59 for the first and second eyes [5]. Choroidal neovascularization (CNV) tends to cause vision loss earlier than macular atrophy, occurring as early as age 45 in the first eye [4]. Some patients may not show CNV in the fellow eye until 3–5 years later [5]. Fundoscopic exami-

nation often reveals a normal fundus in patients younger than 20 years, but most patients exhibit drusen-like deposits at the posterior pole by the third decade, which may not affect visual acuity [5, 7]. These deposits are usually not visualized on fluorescein angiography, although patchy hypofluorescence is observed throughout the retina. Macular atrophy may occur with or without CNV and can result in visual acuity less than 20/200 in the 50s (Figs. 80.1 and 80.2). Some studies have shown that drusen-like deposits may precede CNV by three to twelve years, though CNV can occur in the absence of these deposits [5]. CNV occurs in both eyes in 50% of patients, occurring as early as 37 years and as late as 61 years [5]. CNV has been reported to be recurrent and multifocal in patients with certain mutations [5]. Peripheral atrophy is rare.

Fig. 80.1 Color fundus photo of the right eye of a 54-year-old woman with Sorsby Fundus Dystrophy, showing drusen along the arcades and macular chorioretinal atrophy with scarring and pigmentation. This patient had a history of neovascularization that led to the macular findings.

Fig. 80.2 Color fundus photo of the right eye of another 54-year-old woman with Sorsby Fundus Dystrophy, showing extensive chorioretinal atrophy, with scarring and pigmentation involving the macula and

extending to outside the arcades. There is also atrophy in the retinal periphery, with dense pigmentary changes.

TOPORS encodes E3 ubiquitin-protein ligase Topors, which is an enzyme involved in the proteasomal degradation pathway. Mutations in *TOPORS* cause 1% of autosomal dominant retinitis pigmentosa (adRP) (rod-cone dystrophy) [1–3]. Patients typically present between 10 and 50 years of age with night blindness and peripheral vision loss, although some affected patients may be asymptomatic [1, 2]. Visual acuity is usually maintained until late in the disease process (range: 20/20 to CF). The fundus is characterized by RPE atrophy located uniquely around the retinal vessels (“perivasculature cuff of RPE atrophy”) in very young patients, which progresses with age to diffuse pigment deposits with atrophy (Figs. 81.1 and 81.2) [1]. Patients may also exhibit optic disc pallor and macular RPE atrophy [2]. The full-field ERG reveals a rod-cone pattern of degeneration but exhibits variability [1, 2]. Some patients who carry the mutation may exhibit a normal fundus, even in the context of abnormal ERG parameters [1]. GVF also exhibits a rod-cone pattern, but the extent of visual field loss may vary within the same family [1]. Static perimetry may show loss of sensitivity beyond 10° of eccentricity, with preser-

vation of foveal sensitivities [2]. It has been suggested that the pathogenicity of truncating mutations results from haploinsufficiency [1, 2].

One missense *TOPORS* mutation has been reported to cause autosomal dominant pericentral retinal dystrophy in a family [4, 5]. These patients may be asymptomatic or report central vision defects or pericentral scotomas. Nyctalopia generally begins after age 25 but may not occur until as late as age 50. Color vision abnormalities are uncommon. Fundus findings feature bone spicule deposits near the vascular arcades rather than the mid-periphery, minimal vessel attenuation, and a normal optic disc. Full-field ERG is usually abnormal but is less severely affected than in rod-cone dystrophy as described above and with other forms of adRP. Multifocal ERG usually reveals reduced amplitudes in the macula. Dark-adaptation thresholds may be minimally elevated. GVF reveals a ring scotoma within 30 degrees that spares the fovea. One patient in this family progressed to a clinical picture identical to rod-cone dystrophy, with peripheral bone-spicule deposits and atrophy, vessel attenuation, and eventual involvement of the macula [4].

Fig. 81.1 Color fundus photograph of the left eye of a 27-year-old female patient, showing an unremarkable fundus exam, with only subtle retinal pigment epithelium (RPE) changes and without significant bone spicule pigmentation or atrophy.

Fig. 81.2 Color fundus photograph of the right eye of a 56-year-old patient (father of patient in Fig. 81.1), showing midperipheral RPE atrophy with bone spicule pigment deposits. Some of these deposits and atrophy are near the retinal vasculature. There is also macular RPE depigmentation in the parafovea.

TULP1 encodes tubby-like protein 1, which is a retina-specific protein involved in trafficking of proteins and transport of rhodopsin in photoreceptors. Recessive mutations in *TULP1* cause a range of diseases from Leber congenital amaurosis (LCA) and early-onset retinitis pigmentosa to classic rod-cone dystrophy [1–4].

In one study, Hanein et al. found that mutations in *TULP1* cause 1.7% of LCA. *TULP1*-related LCA patients may show signs of nystagmus, profound visual deficits, and nonrecordable ERGs within the first few months of life. Within their first and second years, patients generally experience nyctalopia more commonly than photophobia. Peripheral visual fields are also reduced [3].

Mutations in *TULP1* cause less than 1% of autosomal recessive retinitis pigmentosa. Patients may exhibit nystagmus (pendular, vertical, or horizontal) shortly after birth as well as visual field loss, poor visual acuity, and night blindness within the first decade of life. Patients may also experience nyctalopia, photoaversion, and head bobbing at early ages. Some patients may have exotropia or early-onset cataracts. Fundus findings may include arteriolar attenuation and typical bone spicule pigmentation in the midperipheral retina (Figs. 82.1a

and 82.2a). RPE mottling, posterior staphyloma, and Fuch's spots have also been reported. Optic disc pallor may also be seen in older patients; one study also found cellophane reflexes from the macula in two patients [5]. Typically, patients exhibit visual acuities less than 20/200 in their 30s and exhibit rod-cone ERG and GVF patterns [1]. Some patients demonstrate non-recordable ERGs for both rod and cone parameters at a younger age. Visual field constriction may progress to absolute scotoma later in the disease process [2, 4, 6–9]. Fundus autofluorescence may show a macular ring of hyperautofluorescence and show hypoautofluorescence in areas of retinal pigment epithelium (RPE) atrophy (Fig. 82.2b). Optical coherence tomography is helpful in demonstrating areas of macular RPE and photoreceptor loss (Fig. 82.1b).

One study described two unrelated patients with a homozygous mutation (p.Arg420Ser) in *TULP1* (inherited through maternal uniparental isodisomy) [10]. While *TULP1* mutations are predominantly associated with rod-mediated diseases, these patients had significant cone dysfunction. They both exhibited progressive loss of visual acuity and bull's-eye maculopathy along with significant loss of cone ERG parameters and central scotomas.

Fig. 82.1 Case summary: 17-year-old with early-onset retinitis pigmentosa. (a) Color fundus photograph of the right eye, showing peripheral retinal atrophy with bone spicule pigment deposits in the midperipheral retina with apparent relative macular sparing. (b)

Spectral domain-optical coherence tomography (SD-OCT), showing loss of the macular ellipsoid zone (EZ) and outer nuclear layer, with a small residual band at the fovea.

Fig. 82.2 Case summary: 21-year-old with Leber congenital amaurosis, onset at birth, visual acuity 0.4 logMAR in the right eye and 0.78 logMAR in the left eye. (a) Color fundus photograph of the right and left eyes, showing macular retinal pigment epithelium (RPE) depigmentation in a ring surrounding the fovea, with midperipheral patchy

RPE atrophy and scant pigment deposits in both eyes. (b) Fundus autofluorescence of the right and left eyes, showing a ring of hyperautofluorescence with spots of hypoautofluorescence corresponding to RPE atrophy outside the arcades.

USH2A encodes usherin. Mutations in *USH2A* are the most common cause of autosomal recessive non-syndromic retinitis pigmentosa (10–15%) [1, 2] and of Usher syndrome type 2 (RP and hearing impairment) [3–6].

In patients with non-syndromic RP, visual acuity is usually maintained until relatively late in the disease course [1, 7–9]. Fundus findings show mild or no pigment deposits, peripheral retinal pigment epithelial atrophy or depigmentation, and cystoid macular edema in some patients (Figs. 83.1a and 83.2). Full-field ERGs and kinetic visual fields are consistent with typical RP. Fundus autofluorescence (FAF) may reveal a peri-macular ring of increased AF (Fig. 83.1b), which constricts over time [8]. Sandberg et al. showed that patients with *USH2A* mutations reach legal blindness (due to either visual field or visual acuity loss) at a median age of 58 and exhibit yearly rates of decline of 2.6%, 7.0%, and 13.2% for visual acuity, visual field area, and 30-Hz flicker amplitude, respectively [10].

USH2A mutations account for about 80% of Usher syndrome type 2. Patients typically present with mild-to-moderate sensorineural hearing loss from birth (more severe

for higher frequency sounds), and are otherwise in good health, with normal vestibular responses. There is evidence suggesting that there may be progression of hearing loss with age in some individuals [11, 12]. The ophthalmic manifestations are characterized by nyctalopia and peripheral visual field loss within the first two decades, which progresses with age, though the rates of progression may vary, with significant intra- and interfamilial phenotypic variability [10, 13–16]. Fundoscopy may demonstrate mild or no pigment deposits (Figs. 83.1a and 83.2), peripheral retinal pigment epithelial atrophy, or depigmentation (Fig. 83.3); a macular hyperautofluorescent ring on fundus autofluorescence imaging (Fig. 83.1b); and cystoid macular edema in some patients. The full-field ERG is often non-recordable [17, 18].

One study described a family with three unique pathogenic variants in *USH2A* in which, depending on which two variants were inherited by an individual, that family member had either nonsyndromic RP or Usher syndrome [8]. However, no reliable genotype-phenotype correlations have been found thus far, as there is significant intra- and interfamilial variability [10, 15, 16].

VCAN encodes four extracellular matrix (ECM) isoforms (due to alternative splicing of introns 7 and 8) that are a component of the vitreous and are likely involved in its maintenance and structural integrity [1, 2]. Mutations, which have only been identified at the splice acceptor region of intron 7 and the splice donor region of intron 8, cause an overexpression of isoforms V2 and V3 and are responsible for Wagner syndrome (WS) [1, 3].

VCAN mutations are responsible for all known cases of Wagner disease, which has an autosomal-dominant pattern of inheritance. The age of onset of the disease is usually during adolescence, but it can also begin during early childhood [4]. Visual acuity and the progression of vision loss has a great deal of inter- and intrafamilial variability [3], but it is

generally within normal range for younger patients (ranging from 20 to 50 years [4]) and severely reduced in older patients [5]. Other features include myopia, early-onset cataracts, progressive nyctalopia, and risk for retinal detachment [1, 3, 4]. Seen on slit-lamp examination, the hallmark feature of Wagner is an optically empty vitreous with strands, membranes, or veils [1, 3, 4]. Chorioretinal atrophy with pigment migration into the retina has also been noted [3], in addition to instances of ectopic foveae, inverted papilla, and uveitis without the formation of synechiae [3, 4]. Scotopic and photopic ERG responses are affected to varying degrees, in a family-specific manner, with reductions in both a- and b-wave amplitudes [2, 3]. Visual field shows ring scotomas with eventual loss of central vision [4].

Fig. 84.1 Case Summary: 31 year old woman with *VCAN* mutations. (a) Color photograph of the right eye, showing diffuse retinal atrophy, more prominent adjacent to the vascular arcades and in the fovea. (b) B-scan of

the right eye, demonstrating vitreous membranes. (c) Spectral Domain Optical Coherence Tomography of the right eye, showing diffuse retinal thinning, loss of the ellipsoid zone, and foveal atrophy.
